Abstract

Dynamic Stochastic General Equilibrium models are often tested against empirical VARs or estimated by minimizing the distance between the model’s and the VAR impulse response functions. These methodologies require that the data-generating process consistent with the DSGE theoretical model has a VAR representation. This paper discusses the assumptions needed for a finite-order VAR(p) representation of any subset of a DSGE model variables to exist. When a VAR(p) is only an approximation to the true VAR, the paper shows that the truncated VAR(p) may return largely incorrect estimates of the impulse response function. The results do not hinge on an incorrect identification strategy or on small sample bias. But the bias introduced by truncation can lead to bias in the identification of the structural shocks. Identification strategies that are equivalent in the true VAR representation perform differently in the approximating VAR.

1 Introduction

An important goal of real and monetary business cycle theoretical research is to explain the empirical evidence on the impact of economic shocks on macroeconomic variables. A vast literature is devoted to building Dynamic Stochastic General Equilibrium (DSGE) models able to explain the impact of a monetary policy shock on output and inflation, or the impact of a technology shock on labor hours. The empirical evidence is often obtained from estimating structural Vector Autoregressions’ (VAR). In part of the literature the structural parameters of a DSGE model are estimated by minimizing the distance between the model’s and the estimated VAR impulse response functions.

A growing number of papers has questioned the ability of estimated VARs to provide reliable guidance to building DSGE models consistent with the data\(^1\). First, a DSGE model implies restrictions in the mapping between economic shocks and observable variables. In linear models (or in linear approximations) these restrictions are summarised by the Vector Moving Average (VMA) representation. If the VMA representation is not invertible a DSGE model does not admit a VAR representation mapping economic shocks to a vector of observable variables and its lags. Fernandez-Villaverde, Rubio-Ramirez and Sargent (2005) discuss the invertibility problem and provide examples of well-specified DSGE models that lack a VAR representation. Second, even if it exists, the VAR representation of a DSGE model may require an infinite number of lags. Yet macroeconomists work with small data samples and are therefore constrained to estimating VARs with a limited number of lags - truncated VARs which only approximate the true VAR representation. Third, the restrictions used to identify structural shocks from the VAR reduced form innovations may be inconsistent with the DSGE model assumptions, leading to a mis-identification problem.

This paper studies finite-order VAR representations of DSGE models and the performance of approximating truncated VARs\(^2\). We derive the DSGE model VARMA representation starting from the state-space representation, and discuss the conditions for a finite-order VAR(p) representation to exist. When a VAR(p) representation does not exist, the paper discusses the empirical relevance of the VAR truncation problem by computing the finite order VAR(p) approximation of a real business cycle model. Truncation affects the impulse response function through two separate channels: the

---

\(^2\)The truncation problem has been acknowledged in the literature (as early as in work by Wallis, 1977) but largely neglected in applied work. See Chari, Kehoe and McGrattan (2005), Cooley and Dwyer (1998), Erceg, Guerrieri and Gust (2004), Faust and Leeper (1997) for discussion within specific models.
VAR(p) erroneously constrains to zero some coefficients in the true VAR representation, and the VAR(p) coefficients can lead to mistaken identification of the structural shocks. Depending on the model parametrization, truncation can lead to large errors through one or both channels. In effect, the truncation bias can cause an identification bias even if the identification strategy is consistent with the theoretical model. Regardless of small sample bias, identification schemes that are equally appropriate in a VAR(∞) perform differently in a truncated VAR.

The paper is related to some recent contributions in the literature. We generalize some results in Chari, Kehoe and McGrattan (2005), who examine a stylized business cycle model, and show that for a standard parametrization the coefficients in the VAR representation converge to zero extremely slowly, making a finite order VAR approximation unsuitable. They find that the impulse response of labor hours to a technology shock identified using long run restrictions in a finite order VAR is a poor approximation to the true magnitude. While we obtain a similar result in a closely related RBC model, we show that the largest part of the approximating error comes from the identification bias. This result is consistent with Christiano, Eichenbaum and Vigfusson (2006), who conclude that when identification is achieved using short run restrictions finite order VARs can achieve a remarkably close approximation to the DSGE model in small sample. Yet, we also find that for some (reasonable) parametrizations of the model, even using the correct theoretical identification matrix and shutting down the identification bias the finite order VAR provides a largely incorrect impulse response function. Erceg, Guerrieri and Gust (2005) study the performance of truncated VAR representations of an RBC model, and conclude that the approximating error stems from the small-sample error impact on the long run identification scheme. In contrast, we show that small sample error is not essential to generate identification bias, and propose a method to measure identification and truncation bias in population.

The paper is organized as follows. Section 2 discusses VAR representations of DSGE models. Section 3 provides conditions for the VAR representation of a DSGE model to be of finite order. Section 4 discusses the performance of truncated VAR and illustrates the impact of truncation and identification bias in an RBC model identified using long run restrictions. Section 5 concludes.
2 VAR representation of DSGE models

A linearized DSGE model can be written as a system of stochastic difference equations. The solution to the system is the recursive equilibrium law of motion:

\[ y_t = \begin{bmatrix} P & Q \end{bmatrix} x_{t-1} + \begin{bmatrix} Q \end{bmatrix} z_t \]  
\[ x_t = \begin{bmatrix} R & S \end{bmatrix} x_{t-1} + \begin{bmatrix} S \end{bmatrix} z_t \]  
\[ Z(L)z_t = \varepsilon_t \]  

where \( x_t \) is an \( n \times 1 \) vector of endogenous state variables, \( z_t \) is an \( m \times 1 \) vector of exogenous state variables, \( y_t \) is an \( r \times 1 \) vector of endogenous variables, \( \varepsilon_t \) is a vector stochastic process of dimension \( m \times 1 \) such that \( E(\varepsilon_t) = 0, E(\varepsilon_t \varepsilon_t') = \Sigma, E(\varepsilon_t \varepsilon_t') = 0 \) for \( r \neq t \) and \( \Sigma \) is a diagonal matrix. \( Z(L) \) is the matrix polynomial \( [I - Z_1 L - \cdots - Z_p L^p] \) in the lag operator \( L \) defining a stationary vector AR(p) stochastic process. King, Plosser and Rebelo (1988) discuss how to obtain the system in eqs. (1) to (3) as the log-linear approximation to the solution of a DSGE model. The equilibrium law of motion of models with linear transition laws and quadratic objective functions takes the same functional form (Hansen and Sargent, 2005).

The polynomial \( Z(L) \) is typically assumed to be of the first order. Additional lags in the process for \( z_t \) can anyway be included in the system by introducing additional state variables in the vector \( x_t \). For \( Z(L) = [I - Z_1 L] \) an alternative way of writing the system in eqs. (1) to (3) is to define the vector \( \tilde{x}_t = [x_{t-1} \ z_t]' \) and the matrices:

\[ \tilde{R} = \begin{bmatrix} R & S Z_1 \\ 0 & Z_1 \end{bmatrix}; \tilde{S} = \begin{bmatrix} S \\ I \end{bmatrix}; \tilde{P} = \begin{bmatrix} P & Q Z_1 \end{bmatrix} \]

Then:

\[ y_t = \tilde{P} \tilde{x}_t + Q \varepsilon_t \]  
\[ \tilde{x}_{t+1} = \tilde{R} \tilde{x}_t + \tilde{S} \varepsilon_t \]  

This is the approach followed, for example, in Fernandez-Villaverde, Rubio-Ramirez and Sargent (2005). All the results in the paper can be obtained using either of the two equilibrium specifications. The specification in eqs. (1) to (3) offers two advantages. First, the endogenous and exogenous state
vectors play a very different role in the finite-order VAR representation of the system. The two vectors have also a different economic interpretation: an economic model is built to explain the dynamics of both $y_t$ and $x_t$ - which typically correspond to observable economic magnitudes. The dynamics of the vector $z_t$ is left unexplained by the model. Second, it will be useful to highlight the role of the matrix $Z(L)$ for the results derived in the paper.

When does the DSGE model equilibrium law of motion map into a finite order VAR representation? Assume $Z(L)$ is the first order lag polynomial $[I - Z_1L]$ and write the system as:

\[
\begin{align*}
Y_t &= AY_{t-1} + Bz_t \\
z_t &= Z_1z_{t-1} + \varepsilon_t \\
Y_t &= \begin{bmatrix} x_t \\ y_t \end{bmatrix} ; A = \begin{bmatrix} R & 0 \\ P & 0 \end{bmatrix} ; B = \begin{bmatrix} S \\ Q \end{bmatrix}
\end{align*}
\]

where the vector $Y'_t = [x_t, y_t]$ has dimension $1 \times n + r$. Assume all the components of the vectors $x_t$ and $y_t$ are observable, and the vector $z_t$ has dimension $m = n + r$. Since the number $n + r$ of observable variables is equal to the number of shocks, if $B^{-1}$ exists:

\[
\begin{align*}
z_t &= B^{-1}Y_t - B^{-1}AY_{t-1} \\
&= Z_1[B^{-1}Y_{t-1} - B^{-1}AY_{t-2}] + \varepsilon_t
\end{align*}
\]

Then a restricted VAR(2) representation for the system (6) is\(^3\):

\[
\begin{align*}
Y_t &= (A + BZ_1B^{-1})Y_{t-1} - (BZ_1B^{-1}A)Y_{t-2} + B\varepsilon_t \\
&= \Gamma_1Y_{t-1} + \Gamma_2Y_{t-2} + \eta_t
\end{align*}
\]

Eq. (7) can be estimated from a data series for $Y_t$. If the model is the true data-generating process, the VAR reduced-form innovations $\eta_t$ are a rotation of the structural shocks vector $\varepsilon_t$ since $\eta_t = B\varepsilon_t$.

If $m > n + r$ a VAR representation of the DSGE model may exist. But it will not be possible to map $\eta_t$ into a higher-dimension vector of orthogonal shocks $\varepsilon_t$. Any mapping from $\eta_t$ to $\varepsilon_t$ will be such that some component of the vector $\varepsilon_t$ can be derived as a linear combination of the remaining

---

\(^3\)Using the system defined in eqs. (4) and (5) would give a VAR(1) representation.
components. If instead \( m < n + r \), as is often the case in DSGE models, the system is singular, preventing likelihood estimation of the VAR. To obtain a non-singular VAR representation of the model (6) some of the observable variables must be dropped from the system so as to satisfy the requirement \( n + r = m \). Omitting a \( r - r_1 \) rows of the \( y \) vector does not affect the VAR(2) representation of any other observable variable. Regardless of which \( r_1 \) rows of \( y \) are included, the VAR(2) representation of any subset \( \hat{Y}_t \) of the vector \( Y_t \) (obtained using the rows of the matrices \( A, B \) corresponding to the \( r_1 + n \) observables and at least all the non-zero columns of \( A \)) is consistent with the DSGE model\(^4\).

### 3 VARMA and VAR representation of DSGE models with unobserved state variables

When a subset of the components in the \( x \) vector is unobservable a VAR representation for \( \hat{Y}_t \) cannot be obtained by eliminating rows from the matrices \( A, B \) and some of the empty columns of \( A \). Does a finite order VAR representation of the DSGE model still exist? If \( n > m \) and \( (n - m) \) components of \( x \) are omitted from the system, the remaining \( n = m \) variables still have a VAR(2) representation, since the omitted variable can be rewritten as a linear combination of lags of the variables included in the VAR. If \( n < m \) excluding components of the \( x \) vector from the list of observable variables implies that a finite order VAR representation for \( \hat{Y}_t \) exists only under the condition stated in the following proposition.

**Proposition 3.1** Let the system in eqs. (1), (2), (3) describe the law of motion of the vectors \( z_t, x_t, y_t \) where \( y_t \) is a vector of dimension \( r \times 1 \), \( x_t \) is a vector of dimension \( n \times 1 \) and \( z_t \) is a vector of dimension \( m \times 1 \). Assume \( m = r \). If the vector \( \hat{Y}_t \) includes all and only the components of \( y_t \):

1. the vector \( \hat{Y}_t \) has a VARMA\((n + pm, n + p(m - 1))\) representation;

2. a finite order VAR representation for \( \hat{Y}_t \) exists if and only if the determinant of \( [G(L)] + PD_G(L)S Q^{-1}L \) is of degree zero in \( L \), where \( G(L) = [I - RL] \) and \( D_G(L) \) is the adjoint matrix of \( G(L) \)

\(^4\)It is assumed that the VAR representation includes at least \( m \) observable variables. Lutkepohl (1993) shows that when the true model is described by the non-singular VAR (7) the data generating process for the observable \( g \times 1 \) vector \( \hat{Y} \) where \( g < m \) is a VARMA\((p,q)\) with \( p \leq 2(n + r) \), \( q \leq 2(n + r) - 2 \).
**Corollary 3.2** The necessary and sufficient condition for existence of a finite order VAR representation can also be stated as the requirement that the determinant of \([I - (R - SQ^{-1}P)L]\) be of degree zero in \(L\).

**Corollary 3.3** If \(n = 1\) or if \(n = m = r\), the vector \(\hat{Y}_t\) has a VARMA\((m+p,m)\) representation.

**Proposition 3.4** The results in Proposition 3.1 also obtain in the case the vector \(\hat{Y}_t\) includes a subset \(n_1 < n\) of the vector \(x_t\) components and a subset \((r - n_1)\) of the vector \(y_t\) components.

Proof of the results is in the Appendix. Proposition 3.1 through 3.4 provide a guide for the researcher trying to estimate a finite-order non-singular VAR consistent with a given DSGE model data-generating process. The VAR estimation assumes either of the two conditions:

(a). The vector \(x_t\) belongs to the set of observable variables included in the data sample.

(a'). The determinant of \([|G(L)| + PD_C(L)SQ^{-1}L]\) is of degree zero in \(L\).

Observability of \(z_t\) is irrelevant for a finite order VAR representation to exist. If the sufficient condition (a) is not met the vector \(\hat{Y}_t\) has a finite order VARMA representation. Under certain conditions, discussed in Fernandez-Villaverde, Rubio-Ramirez and Sargent (2005), the MA component is invertible, and a VAR representation exists. (a’) is the necessary and sufficient condition for the VAR representation to be of finite order. The matrix polynomial \(Z(L)\) does not enter condition (a’).

**4 Finite order approximation to the true VAR process: Truncation and Identification**

When it exists, the VAR representation for \(y_t\) can be written as:

\[
y_t = QZ_1Q^{-1}y_{t-1} + \ldots + QZ_pQ^{-1}y_{t-p} + \]
\[
- [QZ_1Q^{-1}PL + \ldots + QZ_pQ^{-1}PL^p - P] \sum_{j=0}^{\infty} (R - SQ^{-1}P)jL^{j+1}S^{-1}y_t + Qz_t
\]

Eq. (8) is derived from the VAR representation (26) in the Appendix. When conditions (a) or (a’) are not met, a finite order VAR may still be a very good approximation to the true data generating process (8) if the VAR matrix coefficients for longer lags of \(y_t\) are close to zero. This will happen if either the coefficients in the matrix \([QZ_1Q^{-1}PL + \ldots + QZ_pQ^{-1}PL^p - P]\) are close to zero, or if the matrix
\[(R - SQ^{-1}P)^j\] converges to zero fast enough. Asymptotically, the speed at which the VAR polynomial matrices converge to zero depends on the largest eigenvalue of \((R - SQ^{-1}P)\). The polynomial \(Z(L)\) does not appear in the matrix relevant for the convergence speed.

Since the sequence \((R - SQ^{-1}P)^j\) for \(j = 0, 1, ...\) converges to zero, a finite order VAR\((p)\) that well approximates the true VAR process always exists for some sufficiently large value of \(p\). The problem facing economists is whether the number of lags \(p\) to be included is reasonable given the length of economic time series over which VARs are estimated. When estimating VARs consistent with DSGE business cycle models it is standard to assume that including few lags is sufficient to provide a reasonable approximation to the true VAR. This assumption can be misleading. Truncation affects the approximating VAR performance through two separate channels. First, the truncated VAR coefficients are biased: a VAR\((p)\) does not describe the true dynamics of the DSGE model, since all coefficients for lags larger than \(p\) are restricted to be equal to zero. Second, if the VAR coefficients enter in the computation of the matrix identifying structural shocks from reduced form innovations, truncation results in an identification error. Depending on the model none, one or both of these channels - the truncation bias and the identification bias - can prejudice the accuracy of the approximating VAR\((p)\).

The identification bias does not originate in mistaken identification assumptions: the identification scheme may in fact be correct for the true infinite-order VAR representation. Therefore identification schemes that are equivalent in the true VAR have different performance when using a truncated VAR as an approximating model. Finally, truncation and identification bias need not depend on small sample bias of the estimator.

To illustrate the impact of truncation and identification bias we compute from the approximating finite order VAR\((p)\) representation of an RBC model the impulse response function to an identified technology shock, and the structural shocks vector \(\varepsilon_t\). We examine how these magnitudes approximate the true ones. Because the VAR\((p)\) coefficients are population values computed using the projection formulas as in Fernandez-Villaverde et al. (2005), any approximation error does not depend on the variance of the estimator.

### 4.1 A Real Business Cycle Model Example

Consider Hansen’s (1985) indivisible labor model with two exogenous shocks: a non-stationary labor-augmenting technology shock, and a stationary labor supply shock. The planner’s optimal choice for
consumption $C_t$, capital $K_t$, labor $N_t$, and output $Y_t$ maximize the utility function:

$$E_t\sum_{t=1}^{\infty} \beta^t [\ln C_t + AD_t(1 - N_t)]$$

subject to the capital accumulation and production function constraints:

$$K_t = Y_t - C_t + (1 - \delta)K_{t-1} \quad (9)$$

$$Y_t = K_{t-1}^\rho (Z_tN_t)^{1-\rho} \quad (10)$$

The labor-augmenting technology level $Z_t$ and the labor supply shifter $D_t$ follow exogenous stochastic processes:

$$\ln Z_t = \ln Z_{t-1} + \mu_z + \varepsilon_{zt} \quad (11)$$

$$\ln D_t = (1 - \rho_d) \ln D_{t-1} + \mu_d + \varepsilon_{dt} \quad (12)$$

$$\varepsilon_{it} \sim i.i.d. N(0, \sigma_i^2) \quad i = z, d$$

The first order conditions for the planner’s problem are:

$$AD_t = C_t^{-1}(1 - \rho) \frac{Y_t}{N_t} \quad (13)$$

$$1 = \beta E_t \left[ \frac{C_t}{C_{t+1}} \right] \quad (14)$$

$$R_t = \rho \frac{Y_t}{K_{t-1}} + (1 - \delta) \quad (15)$$

where $R_t$ is the gross real interest rate. Equations (9) to (15) describe the equilibrium of the economy. Eq. (12) implies that the log-deviation of the labor supply shock from the steady state, $\ln D_t - \ln \overline{D}$, is an AR(1) process. A technology innovation $\varepsilon_{zt}$ has a permanent impact of the level of technology $Z_t$, but only a transitory impact on the technology growth rate $\ln \left( \frac{Z_t}{Z_{t-1}} \right) = \ln Z_t - \ln Z_{t-1} = \mu_z + \varepsilon_{zt}$. Since $Z_t$ is non-stationary, the steady state level of $Y_t$, $K_t$, $C_t$ depends on the current level of technology, and any innovation $\varepsilon_{zt}$ permanently affects the level of these three variables. The assumption of a utility function logarithmic in $C_t$ and separable in $C_t$ and $Q_w$ implies a balanced growth path exists and the steady state level of $N_t$ is independent of the level of technology. This observation is at the base of the long run identification assumption for the VAR representation.

To solve the model, the non-stationary variables are scaled by the level of technology. The
model defined in terms of $N_t$, $R_t$, $D_t$, $\hat{K}_t = K_t/Z_t$, $\hat{Y}_t = Y_t/Z_t$, $\hat{C}_t = C_t/Z_t$, $\hat{Z}_t = Z_t/Z_{t-1}$ is stationary, and an approximate solution can be obtained by log-linearizing the equilibrium conditions around the steady state. This yields a linear model cast in the form of eqs. (1) to (3). The model parametrization follows the RBC literature (see Erceg, Guerrieri and Gust, 2005). The capital share $\rho$ is set to 0.35. The quarterly depreciation rate for installed capital $\delta$ is assumed equal to 2%. The discount rate $\beta$ is chosen so that in the steady state the annual real interest rate is equal to 3%. The value of the constant $A$ pins down the steady state level of labor, which is set equal to one third of the available time endowment (Hansen, 1985).

The second moment implications of the model depend on the parametrization of the shock processes $Z_t$ and $D_t$. The volatility of the technology innovation is set at $\sigma_z = 0.0148$ following the estimation of the Solow residual $S_t = Z_t^{1-\rho} = Y_t/K_t^\rho N_t^{1-\rho}$ on US postwar data in Erceg, Guerrieri and Gust (2005). The values for $\rho_d$ and $\sigma_d$ are calibrated so that the model can match the second moments of US postwar data. While the level variables $C_t, Y_t, I_t$ are non-stationary in the model, second moments exists for certain ratios of these variables given they all share as a common source of growth the non-stationary technology level. As in King, Plosser and Rebelo (1988) the calibration matches the model’s implications for $\log(C/Y)$, $\log(I/Y)$ and $\log(N)$ to US data. Table 1 compares the second moments under the assumption that $\rho_d = 0.8$ and $\sigma_d = 0.009$. Even with only two shocks and absent any source of nominal rigidity, the model can account fairly well for the volatility of the aggregate ratios and hours. The model underpredicts the volatility of the consumption-output ratio, though its performance improves considerably when compared to the sample starting in 1980:1. As is common in Real Business Cycle models, the correlation between hours and the aggregate ratios is much higher than in the data. The assumption of indivisible labor implies a higher volatility of hours (and productivity) relative to the divisible labor model, for given volatility of $D_t$.

4.2 Consequences of truncation and the role of identification

To write the model in terms of the $P, Q, R, S, Z_1$ matrices define the vectors of endogenous control, endogenous and exogenous state variables respectively as $y_t = [n_t, r_t, \hat{c}_t, \hat{y}_t]^\prime$, $x_t = [\hat{k}_t, z = [\hat{z}_t, d_t]$ where lower-case letters $n_t, r_t, \hat{c}_t, \hat{y}_t, \hat{k}_t, \hat{z}_t, d_t$ stand for log-deviations from the stationary steady state of the variables $N_t, R_t, \hat{C}_t, \hat{Y}_t, \hat{K}_t, \hat{Z}_t, D_t$. The results in the previous section show that any VAR($p$) including $k_t$ among the observables is a correct representation of the model data-generating process, regardless of which additional variables are included from the ones in the vector $y$. Consider instead a truncated VAR(2) for the observable variables $X_t = [\Delta \ln Y_t, n_t]$. The growth rate of output $\Delta \ln Y_t$ is stationary
and can be obtained as a linear combination of the model’s variables: $\Delta \ln Y_t = y_t - y_{t-1} + z_t$. The data-generating process implies the vector $X_t$ has an infinite order VAR representation.

To generate impulse response functions to the structural shocks (that is, to compute the VMA representation) and to estimate the shocks vector from the data, the econometrician needs an estimate of the matrix identifying the orthogonal shocks vector $\varepsilon_t$ from the reduced form shocks $\eta_t$. Define the VAR($p$) representation:

$$X_t = \tilde{\Gamma}_1 X_{t-1} + \ldots + \tilde{\Gamma}_p X_{t-p} + \eta_t$$

and the associated VMA representation for $X_t$:

$$X_t = \eta_t + \hat{\Theta}_1 \eta_{t-1} + \hat{\Theta}_2 \eta_{t-2} + \ldots$$

where $\tilde{\Gamma}_i, \hat{\Theta}_i$ indicate magnitudes related to the finite order VAR approximation, whereas $\Gamma_i, \Theta_i$ indicate the corresponding magnitudes for the true VAR representation. To compute the VMA representation in terms of the structural innovations $\varepsilon_t$ an identifying matrix $\Lambda_0$ such that $\eta_t = \Lambda_0 \varepsilon_t$ is required. Then:

$$X_t = \Lambda_0 \varepsilon_t + \hat{\Theta}_1 \Lambda_0 \varepsilon_{t-1} + \hat{\Theta}_2 \Lambda_0 \varepsilon_{t-2} + \ldots$$

To isolate the impact of truncation and identification bias assume the econometrician sets $\Lambda_0 = \hat{B}$, where the rows of the matrix $\hat{B}$ are such that they map structural shocks into reduced form shocks $\eta_t$ consistently with the DSGE model in the true VAR representation of the data, as in eq. (7). The Appendix shows that $\hat{B}$ is composed of the rows of the matrix $Q$ corresponding to the observable variables. Because the impact of a component of the shocks vector $\varepsilon_i_t$ at time $t$ does not depend on the matrices $\hat{\Theta}_i$, the identifying matrix $\hat{B}$ has the property that the impact response of any variable at time $t$ to a $\varepsilon_i_t$ innovation is exactly the one implied by the theoretical model. But since the VMA representation is obtained from a truncated VAR, the coefficients in the VMA polynomial $\hat{\Theta}(L)$ are biased. This approximation error is generated entirely by the truncation bias.

If the econometrician is not endowed with knowledge of the matrix $\hat{B}$, the biased polynomial matrices $\hat{\Gamma}_1, \hat{\Gamma}_2, \ldots \hat{\Gamma}_p$ may also affect the VAR performance through a second channel: the estimation of the identification matrix $\Lambda_0$. The identification bias can be very large even if the truncation bias is small. Consider the Blanchard and Quah (1989) identification strategy using long run restrictions.
to identify the technology innovation $\varepsilon_{zt}$ from the VAR reduced-form innovations vector $\eta_t$. Since $X_t$ is stationary, neither a technology nor a labor supply innovation has a permanent impact on either component of $X_t$. But any labor supply innovation $\varepsilon_{zt}$ has no long run impact on the level of $\ln Y_t$ itself, while the opposite is true for a technology innovation $\varepsilon_{zt}$. Since $\Lambda_j(1, 2)$ is the impact of $\varepsilon_{zt}$ on $\Delta \ln Y_t$ after $j$ periods, the summation $\Sigma_{j=0}^{\infty} \Lambda_j(1, 2)$ is the long run impact of $\varepsilon_{zt}$ on $\ln Y_t$. The restriction $\Sigma_{j=0}^{\infty} \Lambda_j(1, 2) = 0$ can be used to build the identifying matrix $\Lambda_0$. It implies that the element $(1, 2)$ of the matrix $[\tilde{\Sigma} \Lambda_0]$ be equal to zero since $\Sigma_{j=0}^{\infty} \Lambda_j = \Sigma_{j=0}^{\infty} \tilde{\Theta}_j \Lambda_0 = \tilde{\Theta} \Lambda_0$.

Define the shocks vector $u_t$ as the normalized structural shocks vector $x_w$ so that $H(x_w x_0) = L$. Since the covariance matrix of the reduced form innovation $\eta_t = \Lambda_0 \varepsilon_t$ is equal to $\Omega = \Lambda_0 \Sigma \Lambda_0'$ a Cholesky factorization of $[\tilde{\Sigma} \Omega \tilde{\Theta}] = [\tilde{\Sigma} \Lambda_0 \Sigma^{1/2} \Sigma^{1/2} \Lambda_0']$ provides the lower-triangular matrix $C = \tilde{\Sigma} \Lambda_0 \Sigma^{1/2}$ such that $CC' = [\tilde{\Sigma} \Omega \tilde{\Theta}]$, implying:

$$\tilde{\Lambda}_0 = \Lambda_0 \Sigma^{1/2} = \tilde{\Theta}^{-1} C \quad (16)$$

This is the matrix $\tilde{\Lambda}_0$ such that the element $(1, 2)$ of the matrix $[\tilde{\Sigma} \Lambda_0 \Sigma^{1/2}]$ is zero, as required by the long run identification assumption\(^5\). The first column of the matrix $\tilde{\Lambda}_0$ is all the econometrician needs to know to compute from the VAR the impulse response to a one standard deviation identified technology shock. If the econometrician estimated the infinite order VAR representation of $X_t$, the long run identification restriction would ensure $\Lambda_0 = \tilde{B}$.

Figure 1 shows the impulse response function of $n_t$ obtained from the VAR(2) representation of the vector $X_t$ when the technology shock is identified using the theoretical matrix $\tilde{B}$. The impulse response is constrained to be an exact match to the theoretical one at time $t = 1$ by the matrix $\tilde{B}$, and in the long run by the fact that the approximating VAR is stationary, as is the true model. Even so, the VAR(2) impulse response is a very inaccurate approximation of the true one. After 10 quarters the magnitude of the response is more than 60% smaller than the theoretical response, and it drops to zero after about 25 quarters - implying a much less persistent response of hours compared to the model.

By using the Blanchard and Quah identification strategy, the truncation bias also generates an identification bias. The impulse response (figure 1) drops to zero after about 25 quarters, but also predicts at time 1 an increase in $n_t$ about 75% larger than theoretical response. In a similar model, Chari, Kehoe and McGrattan (2005) obtain an analogous result. This experiment illustrates that the

\(^5\) As noted by Chari, Kehoe and McGrattan (2005), the Cholesky factorization also imposes the long-run sign convention that output growth rises on impact in response to a technology shock.
poor performance of the approximating VAR in Chari, Kehoe and McGrattan (2005) can be largely explained by the identification bias. Contrary to our results, Erceg, Guerrieri and Gust (2005) conclude that the truncation bias is negligible in population, and is essentially a small sample issue.

A closer examination sheds light on the role of identification in the VAR performance. The error in the estimate of $\hat{\lambda}_0$ can originate from two sources: error in estimating $\Omega$ or in estimating $\Sigma$. The covariance matrix $\Omega$ turns out to play a minor role. This is shown by comparing the true shocks vector $\varepsilon_t$ with the orthogonalized shocks estimated from the (correctly identified) VAR:

$$\hat{\varepsilon}_t = \hat{B}^{-1}(X_t - \hat{\Gamma}_1X_{t-1} - \hat{\Gamma}_2X_{t-2})$$

(17)

Table 2 shows that the true and estimated innovations $\varepsilon_t$ are remarkably close. Since the VAR innovations $\eta_t$ are a linear transformation of the structural shocks $\varepsilon_t$, the vector $\hat{\eta}_t$ estimated from the VAR$(p)$ must accurately track the true $\eta_t$, and the estimated covariance matrix $\hat{\Omega}$ must be an accurate approximation to $\Omega$. Figure 2 shows that even if a VAR$(p)$ poorly approximates the true VMA representation, the VAR-estimated shocks vector can still accurately approximate the true shocks. The shocks estimates are calculated using the true data vector $X_t$, therefore the truncation error is not compounded over time, as is the case for the impulse response functions where the estimated response of $X_t$ depends on its the lagged estimates$^6$.

Consider next the role of the VAR$(p)$ coefficients. To build intuition for the result, we examine the case of a finite order VAR where the lag order $p$ is large enough to appeal to large sample properties of the OLS estimator. Asymptotically, the matrices $\hat{\Gamma}_1$, $\hat{\Gamma}_2$ are consistent estimators of the matrices $\Gamma_1$, $\Gamma_2$ from the infinite order VAR representation$^7$. The impulse response function, that is the matrices $\Theta_i$, can be calculated from the recursion:

$$\Theta_i = \sum_{j=1}^{i} \Theta_{i-j}\Gamma_j$$

(18)

$^6$The series of shocks is of interest in its own right, for example for historical decomposition of the shocks driving business cycle fluctuations under the assumption that the observed variables behave consistently with a reference DSGE model (see King and Rebelo, 1998, Ravenna, 2006).

$^7$Convergence in probability of the vector of estimated coefficients in the VAR$(p)$ $[\hat{\Gamma}_1(p), \hat{\Gamma}_2(p), \ldots \hat{\Gamma}_m(p)]$ to the vector $[\Gamma_1, \Gamma_2, \ldots \Gamma_m]$ when the true data generating process is an infinite order VAR is only assured if $p \to \infty$ as the sample size $T$ goes to infinity, albeit at a much slower speed so that $p^3/T \to 0$ (see Lutkepohl, 1993, p.305). Therefore the discussion in the text only applies when the finite order VAR includes a sufficient number of lags. The normal equations giving the $p - lags$ OLS estimator show that $\Gamma_j(i)$ depends on all autocovariances of $Y_t$ up to the $i^{th}$ for any $j$ (see Fernandez-Villaverde et al., 2005). In a subsequent section we show that for the baseline parametrization $\hat{\Gamma}_j(p)$ well approximates $\Gamma_j$ for $p$ equal to 6 and 12.
where $\Gamma_0 = \Theta_0 = I$. Clearly, if the $\Gamma_i$ matrices are very close to zero, also the $\Theta_i$ matrices will be. The matrices $\Gamma_1, \Gamma_2, \Gamma_3$ for example can be easily calculated using eq. (8):

$$
\Gamma_1 = \begin{bmatrix} 
0.0996 & -0.1933 \\
0.1327 & 0.6904 
\end{bmatrix}; \quad \Gamma_2 = \begin{bmatrix} 
0.0958 & -0.0023 \\
0.1276 & -0.0030 
\end{bmatrix}; \quad \Gamma_3 = \begin{bmatrix} 
0.0921 & -0.0022 \\
0.1228 & -0.0029 
\end{bmatrix}
$$

As $i$ increases the matrices $\Gamma_i$ are relatively close to zero, but they converge extremely slowly: the largest eigenvalue of the matrix $(R - SQ^{-1}P)$ is $\lambda = 0.962$. Since the long run identification relies on the infinite summation $\sum_{i=0}^{\infty} \Theta_i$, eq. (18) shows that neglecting the terms $\Gamma_i$ for $i > p$ in the VAR($p$) representation implies the identification matrix is subject to a considerable error. On the contrary, using the correct identification matrix $\hat{B}$ the truncation only feeds through the mistaken restriction $\Gamma_i = 0$ for $i > p$ in eq. (18). The long run identification compounds this mistake because it also makes use of the quantity $\sum_{i=0}^{\infty} \hat{\Theta}_i$. Identification restrictions that are more robust to truncation would reduce the approximation error$^8$.

### 4.3 How model parametrization matters

Consider a model where the labor supply shock is a very persistent process by setting $\rho_d = 0.97$. The impulse response function to a technology shock is not affected by such change. Yet Figure 3 shows that the VAR(2) performance is greatly improved. The impulse response function is remarkably accurate using the theoretical identification matrix.

The improvement in performance can be explained by examining the infinite order VAR matrices $\Gamma_i$. For $i = 1, 2, 3$ they are:

$$
\Gamma_1 = \begin{bmatrix} 
0.0161 & -0.0287 \\
0.0015 & 0.9490 
\end{bmatrix}; \quad \Gamma_2 = \begin{bmatrix} 
0.0154 & -0.0002 \\
-0.0014 & -0.0001 
\end{bmatrix}; \quad \Gamma_3 = \begin{bmatrix} 
0.0147 & -0.0002 \\
-0.0014 & -0.0001 
\end{bmatrix}
$$

The elements of the matrices $\Gamma_i$ are now much closer to zero than in the baseline parametrization. This means that (asymptotically) by restricting $\Gamma_i$ to be equal to zero for $i > p$ a correctly

---

$^8$Christiano, Eichenbaum and Vigfusson (2006), Erceg, Guerrieri and Gust (2005), Faust and Leeper (1997) point out that the difficulty in estimating $\sum_{i=0}^{\infty} \hat{\Theta}_i$ in small sample adversely affect the performance of long run identification restrictions. Sims (1972) first discussed the fact that the sum of an infinite number of coefficients may be extremely difficult to estimate even if the single coefficients are tightly estimated.
identified VAR(p) is a fairly accurate approximation to the true VAR. Nevertheless, the summation \[ \sum_{i=0}^{\infty} \Theta_i \] suffers from a large error. The VAR(p) identified using the long run restriction still tracks poorly the time 1 impact of a technology innovation on hours, though it now implies a very persistent response consistently with the DSGE model.

It may seem puzzling that a change in the parametrization of the labor supply shock that does not affect the dynamics of the model after a technology shock has important implications for the performance of the VAR(2). What is required to the VAR representation for the impulse response to a technology shock to be invariant as \( \rho_d \) varies is that the first column of the matrix \( \Theta_i \hat B = \Theta_i Q \) does not change. The matrix \( \Theta_i \) itself gives the impulse response function of \( X_t \) to a shock in \( \eta_t \), that is, to the linear combination \( \eta_t = Q \varepsilon_t \) of the innovation vector \( \varepsilon_t \). Since the matrix \( Q \) changes across different parametrizations, there is no reason for any of the elements in \( \Theta_i \) to stay constant as \( \rho_d \) increases. As a consequence, also all the elements in the matrices \( \Gamma_i \) change together with \( \rho_d \).

### 4.4 How the number of lags included in the VAR matters

A strategy often used by researchers is to include enough lags in the VAR in the hope that the approximation to the correctly specified infinite order VAR would improve. In the benchmark parametrization, including 6 or 12 lags improves very little the accuracy of the estimated impulse response function when using the long run identification restriction (Chari, Kehoe and McGrattan, 2005, investigate this result in a related model).

In the case of zero identification bias, Figure 4 shows that the impulse response function from a correctly identified VAR(p) is accurate up to the \( p^{th} \) lag (the error depicted in the plot converges to zero as the approximating VAR lag order \( p \) becomes large). This behaviour is easily explained using eq. (18) and considering that asymptotically the matrices \( \hat \Gamma_p \) are consistent estimators of the matrices \( \Gamma_p \). The matrices \( \Theta_j \) in the true VMA representation depend only on the infinite order VAR matrices \( \Gamma_i \) up to \( i = j \). Under the conditions for which the matrices \( \hat \Gamma_i \) from the VAR(p) converge in probability to \( \Gamma_i \), the estimated impulse response function will be correct up to the \( p^{th} \) lag. Yet even including 12 lags has only a small impact in reducing the identification bias.

### 5 Conclusions

This paper discusses the conditions under which a DSGE model has a finite order VAR representation. These conditions are the very implicit assumptions made by the researcher when comparing a DSGE
model impulse response functions to the ones obtained from an estimated VAR. Ordinarily a DSGE model has an infinite order VAR representation, unless the vector of endogenous variables is observable. Observability of the exogenous shocks vector is instead irrelevant.

Economists typically assume that including a small number of lags is enough to provide a reasonable approximation to the true VAR. The paper uses an RBC model to show that this assumption can be misleading. The VAR(p) approximation can provide largely inaccurate estimates of the model impulse response functions. The error in the approximation affects the results through two separate channels: the truncated VAR coefficients are biased, and the truncation error may lead to a identification bias. Depending on the parametrization and the identification strategy none, one or both of these channels will weigh on the accuracy of the approximating VAR(p). This result does not rely on small sample volatility of the estimator, nor on the use of mistaken identification assumptions. Identification strategies which are equally correct in the true VAR representation can perform very differently in the truncated VAR estimate. Even if the impulse response functions can be inaccurate, the VAR(p) can provide a close approximation to the true shocks vector.

These results suggest some caution has to be used by researchers relying on VAR evidence to build DSGE models. VARs have much to tell: they summarize the dynamics of the data with as few restrictions as possible. Compared to alternative econometric procedures, they may be more robust to mis-specification and perform better in small sample. Assuming though that the dynamics VARs describe can always be obtained from the structural models economists are interested in testing is misleading. If economists wish to build DSGE models that can account for the correlations among macroeconomic variables, they should be tested against model-consistent representations of the data.

References

Appendix

Proof of Proposition 3.1 Assume that the lag operator \([I - RL]\) is invertible. Eq. (2) implies \(x_{t-1} = [I - RL]^{-1}SLz_t\). Substituting \(x_t\) in the control variables equation, and since \(\tilde{y}_t = y_t\):

\[
y_t = Qz_t + P[I - RL]^{-1}SLz_t
= Qz_t + PG(L)^{-1}SLz_t\tag{19}
\]

where \(G(L)^{-1}\) is a lag polynomial of potentially infinite order.

VARMA representation for \(Z(L) = I\) If \(z_t = \varepsilon_t\) eq. (19) is a VMA representation of \(y_t\) the process. If \(Q\) is invertible eq. (19) can be written in terms of the reduced form innovations \(\eta_t\):

\[
y_t = \eta_t + PG(L)^{-1}SQ^{-1}L\eta_t
\]

with \(\eta_t = Q\varepsilon_t = Qz_t\). The matrix \(Q\) is the theoretical identifying matrix needed to map structural into reduced form shocks in the true VMA representation of the model. The same result holds when \(z_t\) is an AR(p) process. Assume the lag polynomial \(G(L)\) is invertible. Then we can express the inverse of \(G(L)\) in terms of its determinant \(|G(L)|\), of order \(n\) in the lag operator \(L\), and the adjoint matrix \(D_G(L)\) of order \((n-1)\) in \(L\): \(G(L)^{-1} = D_G(L)|G(L)|^{-1}\). Therefore:

\[
|G(L)|y_t = |G(L)|\eta_t + PD_G(L)SQ^{-1}L\eta_t = G^*(L)\eta_t\tag{20}
\]

Eq. (20) is a VARMA(\(n,n\)). The system (20) is written in final equations form: each component of the vector \(y_t\) depends only on its own lags. Since the matrix for \(L\) of order zero in both lag polynomials \(|G(L)|\) and \(G^*(L)\) is the identity matrix, the VARMA representation is unique.
VAR representation for \( Z(L) = I \) If \( G^*(L) \) is invertible, a VAR representation for \( y_t \) is given by:

\[
|G(L)|G^*(L)^{-1}y_t = \eta_t
\]  

(21)

In general eq. (21) defines an infinite order VAR. Given the assumption of unobservability of \( x_t \), a necessary and sufficient condition for a finite order VAR representation of eq. (20) to exists is that the invertible univariate operator \( |G^*(L)| \) be of degree zero in \( L \). If this is the case, \( G^*(L) \) is a unimodular lag operator and \( G^*(L)^{-1} \) is of finite order (Lutkephol, 1993, p. 245). This property follows from the fact that the inverse of \( G^*(L) \) can be expressed as \( G^*(L)^{-1} = D_{G^*}(L)|G^*(L)|^{-1} \). The adjoint matrix \( D_{G^*}(L) \) is a finite order lag operator, while the inverse of the univariate operator \( |G^*(L)| \) is of infinite order, unless \( |G^*(L)| \) is a constant. The result also holds if the VAR representations of eq. (20) is written in terms of the orthogonal innovations \( z_t \):

\[
|G(L)|y_t = G^*(L)Qz_t
\]  

(22)

Because \( G^*(L) \) and \( Q \) are square matrices with identical dimension, \( |G^*(L)Q| = |G^*(L)||Q| \). Therefore, for the right-hand side polynomial in eq. (22) to be a unimodular operator we still require \( |G^*(L)| \) to be of degree zero in \( L \).

The only case in which the product \( |G(L)||G^*(L)|^{-1} \) in eq. (21) would be of finite order when \( G^*(L) \) is not a unimodular operator occurs when \( G^*(L) = D_G(L) \). But this equality will be true only when all the variables included in the system belong to the state vector. Then \( |G(L)|y_t = D_G(L)S_Lz_t \) and \( G(L)y_t = S_Lz_t \) since \( D_G(L)^{-1}|G(L)| = G(L) \) (where we assumed, WLOG, that \( m = n \)). Similarly, if all the state variables are included in the system, together with the endogenous variables, the system can be rewritten as \([I - AL]Y_t = Bz_t \) where \( Y_t, A, B \) are defined in eq. (6). This process has a VARMA representation \( |G(L)|Y_t = D_G(L)Bz_t \) with \( G(L) = [I - AL] \), and also in this case it obtains \( |G(L)||G^*(L)|^{-1} = |G(L)||D_G(L)|^{-1} = G(L) \) (where we assumed, WLOG, that \( r + m = n \)).

VARMA representation for \( Z(L) \neq I \) Assume \( z_t \) is an invertible \( AR(p) \) process.

Eq. (20) can then be written as \( |G(L)|y_t = G^*(L)QZ(L)^{-1} \varepsilon_t \). Define \( QZ(L)Q^{-1} = [I - QZ_1 Q^{-1} L ... - QZ_p Q^{-1} L^p] = \tilde{Z}(L) \). Then \( QZ(L)^{-1} \varepsilon_t = \tilde{Z}(L)^{-1} \eta_t \) and:

\[
|G(L)|y_t = G^*(L)D_{\tilde{Z}}(L)|\tilde{Z}(L)|^{-1} \eta_t
\]
where $|G^*(L)|$ is of order $nm$ in $L$, $D_{G^*}(L)$ is of order $n(m-1)$ in $L$. Therefore $y_t$ is described by:

$$|\hat{Z}(L)||G(L)|y_t = G^*(L)D_{\hat{Z}}(L)\eta_t$$  \hspace{1cm} (23)

Since $|\hat{Z}(L)|$ is of order $pm$ in $L$, $D_{\hat{Z}}(L)$ is of order $p(m-1)$ in $L$, eq. (23) describes a VARMA($n+pm,n+p(m-1)$) process.

**VAR representation for $Z(L) \neq I$** A VAR representation for $y_t$ is given by:

$$\hat{Z}(L)G^*(L)^{-1}|G(L)|y_t = \eta_t$$  \hspace{1cm} (24)

which will not be of finite order unless the conditions for the VAR defined in eq. (21) to be of finite order are met.  

**Proof of Corollary 3.2** The infinite order VAR defined in eq. (21) can also be obtained without using the VARMA representation. The state space representation implies that $z_{t-1} = Q^{-1}(y_{t-1} - Px_{t-1})$. Therefore

$$x_t = Rx_{t-1} + SQ^{-1}(y_{t-1} - Px_{t-1})$$

$$[I - (R - SQ^{-1}P)L]x_t = H(L)x_t = SQ^{-1}y_{t-1}$$

If the lag polynomial $H(L)$ is invertible, we can write:

$$x_t = H(L)^{-1}SQ^{-1}y_t$$

$$y_t = Qz_t + P[H(L)^{-1}SQ^{-1}]Ly_t$$  \hspace{1cm} (25)

or $y_t = P\sum_{j=0}^{\infty}[R - SQ^{-1}P]^jSQ^{-1}L^{j+1}y_t + \eta_t$. This is the derivation obtained in Fernandez-Villaverde et al. (2005). It is easy to see that to obtain a finite order VAR we need $H(L)$ to be a unimodular operator. This will happen when $|H(L)|$ is of degree zero in $L$, that is, a constant. Since eq. (21) and eq. (25) define the same VAR process, this condition is equivalent to the condition for a unimodular operator established in terms of $|G^*(L)|$. Since the VAR representation (24) can be rewritten using eq. (25) as

$$\hat{Z}(L)[I - P[H(L)^{-1}SQ^{-1}]L]y_t = \eta_t$$  \hspace{1cm} (26)
it follows that an alternative condition for the existence of a finite order VAR representation when \( Z(L) \neq I \) can still be expressed as the requirement that \(|H(L)|\) be of degree zero in \( L \).

\[ G(L)P^{-1}y_t = G(L)P^{-1}Qz_t + SLz_t \]

\[ y_t = PRP^{-1}y_{t-1} + Qz_t + (PS - PRP^{-1})z_{t-1} \]

\[ y_t = PRP^{-1}y_{t-1} + \eta_t + (PSQ^{-1} - PRP^{-1})\eta_{t-1} \]

\[ F(L)y_t = C(L)\eta_t \tag{27} \]

which is the VARMA(1,1) representation of \( y_t \). If \( z_t \) is a vector \( AR(p) \) process, \( QZ(L)^{-1}z_t = \tilde{Z}(L)^{-1}\eta_t \). Then \( F(L)y_t = C(L)z_t = C(L)\tilde{Z}(L)^{-1}\eta_t \). Express the inverse of \( C(L) \) in terms of its determinant \(|C(L)|\), of order \( m \) in \( L \), and the cofactor matrix \( D_C(L) \) of order \( m - 1 \) in \( L \). Then:

\[ F(L)y_t = |C(L)|D_C(L)^{-1}\tilde{Z}(L)^{-1}\eta_t \]

\[ \tilde{Z}(L)D_C(L)F(L)y_t = |C(L)|\eta_t \]

which is the VARMA \((m+p,m)\) representation of \( y_t \). A VARMA \((m+p,m)\) representation also exists if \( n = 1 \). In this case, \([I - RL]^{-1}\) in eq. (19) is a scalar and eq. (27) becomes \( y_t = Ry_{t-1} + \eta_t + (PSQ^{-1} - R)\eta_{t-1} \) which is a VARMA(1,1). The proof then follows the same steps.

\[ \text{Proof of Proposition 3.4} \]

WLOG assume that only the first \( n - 1 \) components of \( x_t \) are observable, and the \( n^th \) component \( \tilde{x}_t \) is unobservable. Define the vector of observable variables \( \tilde{y}_t = [\tilde{x}_t, y_t]^T \) where \( y_t \) is an \( r \times 1 \) vector of endogenous variables, \( x_t = [x_t, \tilde{x}_t]^T \) and \( (n-1) + r = m \). Then \( \tilde{x}_{t-1} = Tx_{t-1} = T[I - RL]^{-1}SLz_t \) where \( T = [0...0 \ 1] \) is a \( 1 \times n \) row vector where the first \( n - 1 \) components are equal to zero. Partition the matrix \( P \) so that \( P = [\overline{P} \ \hat{P}] \) where \( \overline{P} \) is an \( r \times (n - 1) \) matrix and \( \hat{P} \) is an \( r \times 1 \) matrix. The vectors \( y_t \) and \( \overline{x}_t \) can be written as:

\[ y_t = \overline{P}\overline{x}_{t-1} + \hat{P}\hat{x}_{t-1} + Qz_t \]

\[ x_t = \overline{P}\overline{x}_{t-1} + \hat{R}\hat{x}_{t-1} + \overline{S}z_t \]

\( \overline{R} \) is the matrix composed of the first \( n - 1 \) rows and columns of the matrix \( R \), \( \hat{R} \) is a vector...
containing the first \( n - 1 \) components of the last column of \( R \), and \( S \) contains the first \( n - 1 \) rows and all the \( m \) columns of the matrix \( S \). We can then write the process for \( \hat{Y}_t \) as:

\[
\begin{align*}
\hat{Y}_t &= \begin{bmatrix} R & 0 \\ \hat{P} & r \\ \end{bmatrix} \hat{Y}_{t-1} + \begin{bmatrix} S \\ Q \end{bmatrix} z_t + \begin{bmatrix} \hat{R} \\ \hat{P} \end{bmatrix} T[I - RL]^{-1} SL z_t \\
&= \Gamma_1 \hat{Y}_{t-1} + \Gamma_2 z_t + \Gamma_3 G(L)^{-1} SL z_t
\end{align*}
\]

(28)

Defining \( \bar{Y}_t = [I - \Gamma_1 L] \hat{Y}_t \) obtain:

\[
\bar{Y}_t = \Gamma_2 z_t + \Gamma_3 G(L)^{-1} SL z_t
\]

which has the same functional form as eq. (19). The steps of the proof of Proposition 1 follow through unchanged for the observable variable \( \bar{Y}_t \). The variable \( \hat{Y}_t \) will have a VARMA\((n+pm+1,n+p(m-1))\) representation since the observable \( \pi_t \) vector introduces an extra lag. If \( \pi_t = x_t \), eq. (28) is equal to eq. (6) and a finite order VAR representation is immediately available, as derived in the main text.

Note: Standard deviation measured in percent. Relative standard deviation is ratio to standard deviation of log(N). Sample moments for US data are obtained from quarterly per capita values of Y, C, I, N. Y is measured as real GDP net of government consumption expenditures. C is real personal consumption expenditures of non-durables and services. I is real gross private fixed investment. The measure for total per capita labor hours N of all workers is equal to average weekly hours for private industries multiplied by the ratio between the total number of workers employed in the non-farm sector and the civilian non-institutional population. The average weekly hours series starts in 1964:1. All series are seasonally adjusted and obtained from the US Bureau of Labor Statistics.
Table 2
VAR(2) performance - Estimated Identified Shocks Vector \( \hat{\varepsilon}_t \)

<table>
<thead>
<tr>
<th>Shock</th>

<tbody>
<tr>
<td>Correlation with true shock</td>
<td>0.99</td>
<td>0.98</td>
</tr>
<tr>
<td>Relative Root Mean Square Error</td>
<td>3.99%</td>
<td>16.04%</td>
</tr>
</tbody>
</table>

Note: Root mean square distance between the VAR(2)-estimated vector \( \hat{\varepsilon}_t \) and the true vector calculated over 1.5 million observations. The shocks vector \( \hat{\varepsilon}_t \) is obtained from reduced form innovations \( \eta_t \) using the theoretical identification matrix. Data are generated by the DSGE model with labor supply shock autocorrelation \( \rho_d = 0.8 \). The RMSE is scaled by the standard deviation of the corresponding shock.
Figure 1: Impulse response to technology shock $\varepsilon_z$ in correct and approximating VAR(2). VAR coefficients computed from population orthogonality conditions. Scaling is in percentage points. Preference shock autocorrelation $\rho_d = 0.8$. 
Figure 2: Ten year sample path of VAR(2)-estimated series of the shocks vector $\varepsilon$ and true series, $\rho_d = 0.8$. The theoretical matrix from the DSGE model identifies the structural shocks. Scaling is in percentage points.
Figure 3: Impulse response to technology shock \( \varepsilon_{z} \) in correct and approximating VAR(2). VAR coefficients computed from population orthogonality conditions. Scaling is in percentage points. Preference shock autocorrelation \( \rho_{d} = 0.97 \).
Figure 4: Impulse response to technology shock $\varepsilon_{z}$ in correct and approximating VAR(2). VAR coefficients computed from population orthogonality conditions. Scaling is in percentage points. Preference shock autocorrelation $\rho_d = 0.8$. 

True and VAR(p) impulse response of hours to one standard deviation $\varepsilon_{z}$ technology shock
WORKING PAPERS

0527 LUIS J. ÁLVAREZ, PABLO BURRIEL AND IGNACIO HERNANDO: Price setting behaviour in Spain: evidence from micro PPI data.

0528 EMMANUEL DHYNE, LUIS J. ÁLVAREZ, HERVÉ LE BIHAN, GIOVANNI VERONIÈSE, DANIEL DIAS, JOHANNES HOFFMANN, NICOLE JÖNKER, PATRICK LÜNNEMANN, FABIO RUMLER AND JOUKO VILMUNEN: Price setting in the euro area: some stylized facts from individual consumer price data.

0529 TERESA SASTRE AND JOSÉ LUIS FERNÁNDEZ-SÁNCHEZ: Un modelo empírico de las decisiones de gasto de las familias españolas.

0530 ALFREDO MARTÍN-OLIVER, VICENTE SALAS-FUMÁS AND JESÚS SAURINA: A test of the law of one price in retail banking.

0531 GABRIEL JIMÉNEZ AND JESÚS SAURINA: Credit cycles, credit risk, and prudential regulation.

0532 BEATRIZ DE-BLAS-PÉREZ: Exchange rate dynamics in economies with portfolio rigidities.

0533 ÓSCAR J. ARCE: Reflections on fiscalist divergent price-paths.

0534 M.* DE LOS LLANOS MATEA AND MIGUEL PÉREZ: Differences in changes in fresh food prices by type of establishment. (The Spanish original of this publication has the same number.)

0535 JOSÉ MANUEL MARQUÉS, FERNANDO NIETO AND ANA DEL RÍO: Una aproximación a los determinantes de la financiación de las sociedades no financieras en España.

0538 JOSÉ MANUEL CAMPA, LINDA S. GOLDBERG AND JOSÉ M. GONZÁLEZ-MÍNGUEZ: Exchange-rate pass-through to import prices in the euro area.

0539 RAQUEL LAGO-GONZÁLEZ AND VICENTE SALAS-FUMÁS: Market power and bank interest rate adjustments.

0540 FERNANDO RESTOY AND ROSA RODRÍGUEZ: Can fundamentals explain cross-country correlations of asset returns?

0541 FRANCISCO-ALONSO AND ROBERTO BLANCO: Is the volatility of the EONIA transmitted to longer-term euro money market interest rates?

0601 ARTURO GALINDO, ALEJANDRO IZQUIERDO AND JOSÉ MANUEL MONTERO: Real exchange rates, dollarization and industrial employment in Latin America.

0602 JUAN A. ROJAS AND CARLOS URRUTIA: Social security reform with uninsurable income risk and endogenous borrowing constraints.

0603 CRISTINA BARCELÓ: Housing tenure and labour mobility: a comparison across European countries.

0605 RICARDO GIMENO AND CARMEN MARTÍNEZ-CARRASCAL: The interaction between house prices and loans for house purchase. The Spanish case.

0606 JAVIER DELGADO, VICENTE SALAS AND JESÚS SAURINA: The joint size and ownership specialization in banks’ lending.

0607 ÓSCAR J. ARCE: Speculative hyperinflations: When can we rule them out?

0609 JUAN AYUSO AND FERNANDO RESTOY: House prices and rents in Spain: Does the discount factor matter?

0610 ÓSCAR J. ARCE AND J. DAVID LÓPEZ-SALIDO: House prices, rents, and interest rates under collateral constraints.

0611 ENRIQUE ALBEROLA AND JOSÉ MANUEL MONTERO: Debt sustainability and procyclical fiscal policies in Latin America.

1. Previously published Working Papers are listed in the Banco de España publications catalogue.
0612 GABRIEL JIMÉNEZ, VICENTE SALAS AND JESÚS SAURINA: Credit market competition, collateral and firms’ finance.

0613 ÁNGEL GAVILÁN: Wage inequality, segregation by skill and the price of capital in an assignment model.

0614 DANIEL PÉREZ, VICENTE SALAS AND JESÚS SAURINA: Earnings and capital management in alternative loan loss provision regulatory regimes.

0615 MARIO IZQUIERDO AND AITOR LACUESTA: Wage inequality in Spain: Recent developments.

0617 JAVIER DÍAZ-CASSOU, ALCIA GARCÍA-HERRERO AND LUIS MOLINA: What kind of capital flows does the IMF catalyze and when?

0618 SERGIO PUENTE: Dynamic stability in repeated games.

0619 FEDERICO RAVENNA: Vector autoregressions and reduced form representations of DSGE models.
