Abstract

We analyze optimal monetary policy in a model with two distinct financial frictions. First, borrowing is subject to collateral constraints. Second, credit flows are intermediated by monopolistically competitive banks, thus giving rise to endogenous lending spreads. We show that, up to a second order approximation, welfare maximization is equivalent to stabilization of four goals: inflation, output gap, the consumption gap between constrained and unconstrained agents, and the distribution of the collateralizable asset between both groups. Following both financial and non-financial shocks, the optimal monetary policy commitment implies a short-run trade-off between stabilization goals. Such policy trade-offs become amplified as banking competition increases, due to the fall in lending spreads and the resulting increase in financial leveraging.

Keywords: banking competition, lending spreads, collateral constraints, monetary policy, linear-quadratic method.

1 Introduction

In this paper we provide a theoretical framework for the analysis of the optimal conduct of monetary policy in the presence of financial frictions. Both optimal monetary policy and the macroeconomic effects of financial frictions have attracted much attention in recent times. However, much less effort has been devoted to exploring the connections between both fields in the context of modern dynamic stochastic general equilibrium (DSGE) models.

Here we perform such an exploration in the framework of a model economy featuring two distinct financial frictions: collateral constraints and endogenous bank-lending spreads. In this way, our setup addresses two of the most prominent hypotheses in the macroeconomic literature on financial frictions: one that emphasizes the role of endogenous collateral constraints and fluctuations in asset prices (Kiyotaki and Moore, 1997; Iacoviello, 2005), and another one that stresses the role of endogenous lending spreads, as exemplified by the "financial accelerator" literature (Bernanke and Gertler, 1989; Bernanke, Gertler and Gilchrist, 1999) and by the recent literature on banking and macroeconomics (Goodfriend and McCallum, 2007).

Specifically, we consider an economy in which consumers are divided into households and entrepreneurs, where the former are assumed to be relatively more patient and therefore act as savers. Unlike in most of the literature, savers do not lend directly to borrowers. Instead, they provide banks with deposits that are then used to make loans to entrepreneurs. Banks are assumed to have some monopolistic power in the loans market. In particular, following Andrés and Arce (2008) we assume that a fixed number of identical banks compete to attract investors as in the spatial competition model of Salop (1979). In this framework, each bank is able to charge a positive lending spread on the deposit rate. Entrepreneurs face endogenous credit limits that link their borrowing capacity to the expected value of their real estate holdings, which are assumed to be the only collateralizable asset. Real estate can also be used by entrepreneurs as commercial property for production purposes, and by households in the form of residential property.

In our framework, borrowers optimally select in every period their lending bank and the size of the loan. Both decisions determine the two margins of the demand for loans: the extensive margin (the market share of each bank) and the intensive margin (the volume of funds demanded by each borrower). Each bank sets its profit-maximizing lending rate taking into account that a higher rate raises unit margins but reduces both its market share and the demand for funds by each customer. Due to the effect of collateral constraints, entrepreneurs’ demand for loans depends not only on loan rates but also on expected real estate prices and on the pledgeability ratio, which is the maximum fraction of the expected resale value of a borrower’s asset holdings.
that can be pledged as collateral. These factors, along with the number of competing banks, are the major determinants of the optimal lending margins, through their influence on the elasticity of the demand schedule faced by each individual bank. In particular, equilibrium lending margins are lower when real estate prices are expected to rise, when borrowing constraints are looser, or when there is a larger pool of banks. Further, there is also a positive relationship between the monetary policy rate, which corresponds to the banks’ marginal cost, and the lending margin; this generates a monetary policy accelerator, since a change in the policy rate produces a more than one-for-one change in the lending rate. Also, our economy features two familiar nominal frictions: nominal (non-state-contingent) debt and staggered nominal price adjustment à la Calvo (1983), both of which open two additional channels of influence for monetary policy.

Our main objective is to understand the nature of optimal monetary policy in this framework. With this aim we follow the welfare-based linear-quadratic approach pioneered by Rotemberg and Woodford (1997).\footnote{See Woodford (2003), Benigno and Woodford (2003, 2008) and Benigno and Benigno (2003) for extensive applications of the linear-quadratic approach to the study of optimal monetary policy.} This approach consists of deriving a second-order approximation of the aggregate welfare criterion, and a first-order approximation of the equilibrium conditions. The central bank’s optimal monetary policy commitment is the one that maximizes the quadratic welfare criterion subject to the linear equilibrium constraints. This approach allows us to clarify what the stabilization goals of the central bank are, and what trade-offs exist between these goals. We first show that the central bank’s quadratic welfare criterion features four stabilization goals: inflation, the output gap, the difference in consumption between households and entrepreneurs (or consumption gap) and the inefficiency in the distribution of real estate between both groups (or housing gap). The first two, inflation and the output gap, are related to the existence of staggered price adjustment and are therefore standard in the New Keynesian literature. The last two are novel and are directly related to the existence of financial frictions. Regarding the consumption gap, collateral constraints prevent constrained consumers from smoothing their consumption the way unconstrained consumers do. In particular, we show that in equilibrium entrepreneurs consume a constant fraction of their net worth, which in this framework is a fairly volatile variable. This gives rise to inefficient risk sharing between both consumer types. Regarding the housing gap, the distribution of real estate between both groups will generally be inefficient, because entrepreneurs’ demand for real estate is distorted by the latter’s role as collateral. We then use the log-linear equilibrium constraints to illustrate some of the trade-offs among stabilization goals. We show that the consumption gap arises as an endogenous cost-push term in the New Keynesian Phillips curve;
that is, inefficient risk-sharing creates a short-run trade-off between inflation and output gap.\footnote{2} In addition, we show that narrowing the consumption and housing gaps requires the central bank to manipulate the path of entrepreneurial net worth, which in turn implies inefficient fluctuations in inflation and the output gap. Therefore, the optimal policy commitment must yield a compromise between stabilization goals.

In order to gain further insight on the nature of optimal policy, we simulate the effects of both financial and non-financial shocks in a calibrated version of our model economy. In each case, we compare the impulse-responses under the optimal policy with those under strict inflation targeting, which is the optimal policy in the standard New Keynesian model. Consider for instance a negative TFP shock, as an example of a non-financial shock. The fall in TFP produces a fall in entrepreneurs’ demand for commercial property that is amplified by the effect of collateral constraints. Real estate prices fall, which together with the fall in entrepreneurs’ real estate holdings produces a sharp drop in their net worth and hence in their consumption. Under strict inflation targeting, these forces tend to give rise to large consumption and housing gaps. In order to counteract the emergence of such gaps, the optimal policy engineers a sharper cut in the policy rate, which banks pass on to nominal loan rates.\footnote{3} This contains the fall in demand for commercial real estate (hence narrowing the housing gap) and in real estate prices. The resulting improvement in entrepreneur net worth narrows the consumption gap. The more aggressive policy response comes at the cost of generating temporary increases in inflation and the output gap, but these are very short-lived thanks to the improved output-inflation trade-off allowed for by the smaller consumption gap.\footnote{4} Now consider an exogenous reduction in the pledgeability ratio, or credit crunch, as an example of a financial shock. The analysis bears some similarities with that of a productivity shock, but it also differs in some important respects. The fall in the pledgeability ratio has a direct counter-cyclical effect on lending spreads, which amplifies the contractionary effects of the credit-crunch. A lower pledgeability ratio implies that real estate is less valuable as a collateral, leading again to an excessive fall in entrepreneurs’ demand for commercial property (i.e. a positive housing gap) and hence in real estate prices. However, the negative effect of lower real estate wealth on entrepreneurs’ net worth is now

\footnote{2}{The intuition for this result is the following. Because of inefficient risk-sharing between consumer groups, the labor demand curve tends to shift by more after a shock than the labor supply curve. This makes it impossible to prevent fluctuations in labor hours (which are proportional to the output gap in our framework) under a policy of strict inflation targeting.}

\footnote{3}{Under our baseline calibration, the endogenous response of lending margins to productivity shocks is fairly small, such that nominal loan rates respond almost one for one with the policy rate. See Andrés & Arce (2008) for a detailed explanation of the effect of productivity shocks on lending margins.}

\footnote{4}{Interestingly, the increase in inflation reinforces the improvement in entrepreneurs’ net worth through a debt deflation effect. Quantitatively, we find however that this effect is small.}
counteracted by a lower debt burden (a direct consequence of the credit crunch). As a result, the consumption gap does not respond as strongly as in the case of productivity shocks, such that the optimal response to the credit crunch basically consists of narrowing the housing gap. Again, the optimal commitment is implemented via a sharper cut in the policy rate.

We are also interested in understanding how the degree of banking competition affects the severity of the trade-offs just discussed. With this purpose, we consider a counter-factual scenario in which the banking sector becomes perfectly competitive, and then compare the volatility of stabilization goals and the associated welfare losses in this and our baseline scenario. We find that welfare losses are higher with perfect banking competition, both under the optimal commitment and (especially) under suboptimal policy rules, such as inflation or output-gap targeting. The reason is that, as lending spreads fall, entrepreneurs can borrow more for given expected real estate wealth. This allows them to increase their real estate holdings without making use of their net worth; that is, their leverage ratio increases. This makes their net worth more sensitive to fluctuations in real estate prices, which in turn amplifies fluctuations in the consumption and housing gaps. This mechanism operates regardless of the nature of shocks. However, in the case of credit crunch shocks it is counteracted by an opposing force: lending margins become zero under perfect competition, and so the amplifying effect of the counter-cyclical response of lending margins to such shocks disappears.

Our analysis is related to recent work by Cúrdia and Woodford (2008; CW, for short), who focus on the design of optimal monetary policy rules in a model in which a positive spread exists between lending and deposit rates. CW assume that the lending spread is determined by an ad-hoc function of banks’ loan volume, aimed at capturing the costs of originating and monitoring loans. We differ from CW in two important respects regarding the nature of credit frictions. First, we model credit spreads as arising endogenously in an environment in which banks enjoy some monopolistic power in the loans market. Second, we subject borrowers to endogenous collateral constraints, thus providing a link between asset prices and the borrowing capacity of constrained consumers. As in CW, we cast our optimal policy problem in a linear-quadratic representation, motivated by its potential for delivering analytical results. Importantly, both CW and our paper find that cyclical fluctuations in lending spreads have minor quantitative effects on the nature of optimal monetary policy design. However, in our model the average level of lending spreads has non-negligible effects that arise from the interaction between spreads and collateral constraints, a channel which is missing in CW.

Also related is the work of Monacelli (2007), who analyzes the Ramsey optimal monetary policy in a model with collateral constraints and quadratic price adjustment costs. He finds a trade-off between stabilizing inflation and relaxing collateral constraints, and studies the
dependence of optimal inflation volatility on a number of structural parameters. De Fiore, Teles and Tristani (2009) explore optimal monetary rules in a model where firms’ assets and liabilities are denominated in nominal terms and predetermined. Our model also incorporates predetermined nominal debt that, as in their model, works to amplify or dampen shocks. However, our focus is rather on the consequences of other forms of financial frictions, especially collateral constraints and endogenous lending spreads, for the optimal conduct of monetary policy. Finally, De Fiore and Tristani (2009) have recently explored optimal monetary policy in an environment where lending spreads are the result of costly state verification problems, as in the financial accelerator theory in Bernanke and Gertler (1989).

The rest of the paper is organized as follows. Section 2 describes the model. In section 3 we analyze the efficient equilibrium, which corresponds to the normative benchmark for the optimizing central bank. We derive the optimizing monetary policy criterion in section 4 and discuss the several trade-offs faced by the monetary authority. In section 5 we use some calibrated versions of the model to perform a number of quantitative exercises, in order to illustrate the working of optimal and suboptimal monetary rules. Section 6 concludes.

2 Model

In this section we describe a model economy that relies on Iacoviello (2005) and Andrés and Arce (2008). The population of consumers, whose size is normalized to 1, is composed of two types of agents: there is a fraction $\omega$ of households and a fraction $1 - \omega$ of entrepreneurs. The latter are assumed to be more impatient than the former. This produces credit flows between both groups which are intermediated by monopolistically competitive banks. A sector of monopolistic final goods producers transforms the homogenous intermediate good produced by the entrepreneurs into differentiated final goods, which are then sold to consumers. We now analyze the problem of each type of agent.

2.1 Households

The representative household maximizes the following welfare criterion, 

$$E_0 \sum_{t=0}^{\infty} \beta^t \left( \log c_t - \frac{(h_t^e)^{1+\phi}}{1+\phi} + \theta_t \log h_t \right),$$

where $c_t$ are units of a Dixit-Stiglitz basket of final consumption goods, $l_t^s$ is labor supply, $h_t$ are units of housing, $\vartheta_t = \vartheta \exp(z_t^h)$ is an exogenously time-varying weight on utility from housing services (where $z_t^h$ follows a zero-mean AR(1) process) and $\beta \in (0, 1)$ is the household’s subjective discount factor. Maximization is subject to the following budget constraint expressed in real terms,

$$w_t l_t^s + \frac{\Omega_t^h + \Omega_t^f}{P_t} + s_t + \frac{R_{t-1}^D}{\pi_t} d_{t-1} = c_t + p_t^h ((1 + \tau^h) h_t - h_{t-1}) + d_t,$$

where $w_t$ is the hourly wage, $\Omega_t^h$ and $\Omega_t^f$ are lump-sum nominal profits from the banking and final goods sectors, respectively, and $s_t$ are lump-sum subsidies from the government. We assume that nominal, risk-free, one-period bank deposits are the only financial asset available to households, where $d_t$ is the real value of deposits at the end of period $t$, $R_{t-1}^D$ is the gross nominal deposit rate and $\pi_t = P_t/P_{t-1}$ is the gross inflation rate, where $P_t$ is the Dixit-Stiglitz aggregate price index. Households can also buy and sell real estate at a unit price $p_t^h$ (measured in terms of consumption goods). End-of-period housing wealth is taxed at the rate $\tau^h$ (the role of which is discussed later on). We assume that real estate does not depreciate. The first order conditions of this problem can be expressed as

$$w_t = c_t (l_t^s)^{\varphi},$$

$$\frac{1}{c_t} = \beta R_{t-1}^D E_t \left\{ \frac{1}{c_{t+1}} \frac{P_{t+1}}{P_t} \right\},$$

$$\frac{(1 + \tau^h)}{c_t} \frac{p_t^h}{h_t} = \frac{\vartheta_t}{h_t} + \beta E_t \frac{p_{t+1}^h}{c_{t+1}}.$$

### 2.2 Entrepreneurs (intermediate good producers)

Entrepreneurs produce a homogenous intermediate good that is sold under perfect competition to a final goods sector. They operate a Cobb-Douglas production technology,

$$y_t = e^{a_t} \left( \frac{1}{l_t^d} \right)^{1-\nu} \left( h_{t-1}^e \right)^{\nu},$$

where $y_t$ is output of the intermediate good, $l_t^d$ is labor demand, $h_{t-1}^e$ is the stock of commercial real estate and $a_t$ is a zero-mean AR(1) exogenous productivity process. Entrepreneurs also demand consumption goods and loans. The budget constraint of the representative entrepreneur
is given by

$$b_t + (1 - \tau^c) \left(p^I_t y_t - w_t h^I_t \right) = c^e_t + p^h_t (h^e_t - h^e_{t-1}) + \frac{R^L_{t-1}}{\pi_t} b_{t-1},$$

(5)

where $b_t$ is the real value of one-period nominal loans at the end of period $t$, $R^L_t$ is the gross nominal loan rate, $p^I_t$ is the real price of the intermediate good, $\tau^c$ is a tax rate on entrepreneur profits (the role of which is explained below) and $c^e_t$ is entrepreneur consumption. Banks impose a collateral constraint on entrepreneurs: the nominal loan gross of interest payments cannot exceed a certain fraction (the pledgeability ratio) of the expected nominal resale value of the entrepreneur’s real estate holdings. The collateral constraint can be expressed in real terms as,

$$b_t \leq m_t E_t \frac{\pi_{t+1}}{R^L_t} p^h_t h^e_t,$$

(6)

where $m_t = m \exp(z^m_t)$ is the exogenously time-varying pledgeability ratio and $z^m_t$ is a zero-mean AR(1) process. In order to obtain a loan, the entrepreneur must first travel to a bank, incurring a utility cost which is proportional to the distance between hers and the bank’s location. We assume that entrepreneurs and banks are uniformly distributed on a circle of length one. Subject to (4), (5) and (6), an entrepreneur located at point $k \in (0, 1]$ maximizes

$$E_0 \sum_{t=0}^{\infty} (\beta^c)^t \left( \log c^e_t - \alpha d_t^{k,i} \right),$$

where $d_t^{k,i}$ is the distance between the entrepreneur and the lending bank (denoted by $i$), and $\alpha$ is the utility cost per distance unit.\(^5\) Entrepreneurs are assumed to be more impatient than savers: $\beta^c < \beta$. The first order conditions of this problem are

$$w_t = p^I_t (1 - \nu) \frac{y_t}{c_t^e},$$

(7)

$$\frac{1}{c^e_t} = \beta^c R^L_t E_t \left\{ \frac{1}{c^e_{t+1}} \frac{P_t}{P_{t+1}} \right\} + \xi_t,$$

(8)

$$\frac{p^h_t}{c^e_t} = E_t \frac{\beta^c}{c^e_{t+1}} \left\{ (1 - \tau^c) p^I_{t+1} \nu \frac{y_{t+1}}{h^I_t} + p^h_{t+1} \right\} + \xi_t m_t E_t \frac{\pi_{t+1}}{R^L_t} p^h_{t+1},$$

(9)

where $\xi_t$ is the Lagrange multiplier on the collateral constraint and $p^I_t \nu y_t / h^e_{t-1}$ is the marginal revenue product of commercial real estate. When binding ($\xi_t > 0$), the collateral constraint

---

\(^5\)This simple device is meant to motivate the existence of some monopoly power on the part of banks. See Andrés and Arce (2008) for a discussion on the foundations of this assumption.
has two effects on the entrepreneur’s decisions: first, it prevents them from smoothing their consumption the way households do (equation 8); second, it increases the marginal value of real estate due to its role as collateral (equation 9).

Equations (8) and (2) imply that in the steady state the borrowing constraint is binding ($\xi_{ss} > 0$, where the $ss$ subscript denotes steady state values) if and only if $\beta R_D > \beta^e R_L$, which holds under our subsequent calibration. Provided that the fluctuations in the relevant variables around their steady state are sufficiently small, the borrowing constraint will also bind along the dynamics; that is, equation (6) will hold with equality. In that case, it is possible to show that entrepreneur consumption equals\(^6\)

$$c_t^e = (1 - \beta^e) \left[ (1 - \tau^e) \nu p_t^l y_t + p_t^h h_{t-1}^e - \frac{R_{t-1}^L}{\pi_t} b_{t-1} \right].$$

That is, the entrepreneur always consumes a fraction $1 - \beta^e$ of her real net worth, which is the sum of after-tax real profits, $(1 - \tau^e) \nu p_t^l y_t$, and commercial real estate wealth, $p_t^h h_{t-1}^e$, minus real debt repayments, $R_{t-1}^L b_{t-1}/\pi_t$.

### 2.3 Banks

Banks are assumed to intermediate all credit flows between households (savers) and entrepreneurs (borrowers). We assume that banks are perfectly competitive on the deposits market, and so they take as given the nominal deposit rate, $R_D$, which is set by the central bank. However, competition in the loans market is imperfect, so that each bank enjoys some monopolistic power. In order to model imperfect competition in the loans market we use a version of Salop’s (1979) circular-city model. A discrete number $n$ of banks are located symmetrically on the unit circle and their position is time-invariant, whereas entrepreneurs’ locations vary each period according to an iid stochastic process.\(^7\) Bank $i \in \{1, 2, ..., n\}$ chooses the gross nominal interest rate on its loans, $R_t^L(i)$, to maximize

$$E_t \sum_{s=0}^{\infty} \beta^s \frac{c_t}{c_{t+s}} \frac{\Omega_{t+s}(i)}{P_{t+s}}$$

where $\beta^s c_t/c_{t+s}$ is the time $t + s$ stochastic discount factor of the households (who are assumed to own the banks) and $\Omega_{t+s}(i)$ is the bank’s nominal profit flow. Denoting by $B_t(i)$ and $D_t(i)$

---

\(^6\)See the proof in the Appendix.

\(^7\)This last assumption removes the possibility that banks exploit strategically the knowledge about the current position of each entrepreneur to charge higher rates in the future.
the nominal stock of loans and deposits of bank $i$ at the end of time $t$, respectively, we can write its flow of funds constraint as

$$\Omega_t(i) + B_t(i) + R^{D}_{t-1}D_{t-1}(i) = R^{L}_{t-1}(i)B_{t-1}(i) + D_t(i).$$

Further, bank $i$ must also obey the balance-sheet identity, $D_t(i) = B_t(i)$. This implies that period $t$ nominal profits are simply $\Omega_t(i) = (R^{L}_{t-1}(i) - R^{D}_{t-1})B_{t-1}(i)$. To solve for the bank’s optimal loan rate, it is convenient to express its loan volume in real terms as

$$\frac{B_t(i)}{P_t} = b_t(i)\tilde{b}_t(i),$$

where $b_t(i)$ is the intensive business margin (the size of each loan) and $\tilde{b}_t(i)$ is the extensive business margin (the number of customers, or market share).\(^8\) The first order condition of this problem can be written as

$$R^{L}_t(i) = R^{D}_t + \frac{1}{\Lambda_t(i) + \check{\Lambda}_t(i)},$$

where $\Lambda_t(i) \equiv [-\partial b_t(i)/\partial R^{L}_t(i)]/b_t^i$ and $\check{\Lambda}_t(i) \equiv [-\partial \tilde{b}_t(i)/\partial R^{L}_t(i)]/\tilde{b}_t(i)$ are the semi-elasticsities of the intensive and the extensive business margins, respectively. Thus the spread between the lending and the deposit rate is a negative function of the bank’s market power, as represented by the semi-elasticsities of individual loan size and market share.

As shown in Andrés and Arce (2008), in a symmetric equilibrium (i.e. $R^{L}_t(i) = R^{L}_t \forall i$), the optimal nominal loan rate can be expressed as

$$R^{L}_t = R^{D}_t + \frac{R^{D}_t - m_tE_t(\pi_{t+1}p^h_{t+1}/p^h_t)}{\eta m_tE_t(\pi_{t+1}p^h_{t+1}/p^h_t) - R^{D}_t}R^{D}_t,$$

where

$$\eta \equiv 1 + \frac{n}{\alpha(1 - \beta^c)}.$$

Therefore, the lending spread is decreasing in expected house price inflation, $E_t(\pi_{t+1}p^h_{t+1}/p^h_t)$, the pledgeability ratio, $m_t$, and the degree of banking competition, as captured by the ratio $n/\alpha$; and it is increasing in the nominal deposit rate, $R^{D}_t$. The intuition for these effects is the following. An increase in expected house price inflation or in the pledgeability ratio increase entrepreneurs’ borrowing capacity. As their indebtedness rises, their demand for loans becomes more elastic, which reduces banks’ market power and compresses lending spreads. Similarly,

\(^8\)See Andrés and Arce (2008) for analytical derivations of both margins.
as entrepreneurs become more indebted, the utility cost of servicing the debt becomes more important in the choice of bank relative to the distance utility cost. As a result, small changes in loan rates lead to large flows of customers in search for the lowest loan rate. This reduces the elasticity of the extensive business margin and hence pushes lending spreads down. Similar intuitions can be provided regarding the effects of the nominal deposit rate. Finally, an increase in the degree of banking competition (i.e. a rise in $n/\alpha$) compresses lending spreads through an increase in the elasticity of banks’ market share with respect to the lending rate.

In the symmetric equilibrium, each bank has $\tilde{b}_i(i) = (1 - \omega)/n$ customers and each loan equals $b_i(i) = b_t$ in real terms, for all $i \in \{1, 2, ..., n\}$. Therefore, aggregate real profits in the banking sector equal $\Omega_t^b/P_t = (R_{t-1}^L - R_{t-1}^P) b_t (1 - \omega)$.

### 2.4 Final goods producers

There exist a measure-one continuum of firms that purchase the intermediate good from entrepreneurs and transform it one-for-one into differentiated final good varieties. For these firms, the real price of the intermediate good, $p_t^i$, represents the real marginal cost. Cost minimization by consumers implies that each final good producer $j \in [0, 1]$ faces the following demand curve for its product variety,

$$y_t^j(j) = \left(\frac{P_t(j)}{p_t^j}\right)^{-\varepsilon} y_t^j,$$

where $P_t(j)$ is the firm’s nominal price, $\varepsilon > 1$ is the elasticity of substitution between final good varieties and

$$y_t^j = \omega c_t + (1 - \omega) c_t^\varepsilon$$

is the aggregate demand for final goods. As is standard in the New Keynesian literature, we assume staggered nominal price adjustment à la Calvo (1983). Letting $\theta$ denote the constant probability of price adjustment, the optimal price decision of the price-setting firms is given by

$$E_t \sum_{s=0}^{\infty} (\beta \theta)^s \frac{c_t}{c_{t+s}} \left\{ (1 + \tau) \frac{\tilde{P}_t}{P_{t+s}} - \frac{\varepsilon}{\varepsilon - 1} p_{t+s}^i \right\} P_{t+s}^c y_{t+s}^i = 0,$$

where $\tau > 0$ is a subsidy rate on the revenue of final goods producers (the role of which is explained below) and $\tilde{P}_t$ is the optimal price decision. Under Calvo price adjustment, the aggregate price index evolves as follows,

$$P_t = \left[ \theta P_{t-1}^{1-\varepsilon} + (1 - \theta) \tilde{P}_t^{1-\varepsilon} \right]^{1/(1-\varepsilon)}.$$
Aggregate nominal profits in the final goods sector equal $\Omega_t^f = \int_0^1 \left[ (1 + \tau) P_t(j) - P_t p_t^f \right] y_t^f(j) dj$.

2.5 Market clearing

Total supply of the intermediate good equals $(1 - \omega) y_t$. Total demand from final good producers equals $\int_0^1 y_t^f(j) dj$, where each firm’s demand is given by (13). Equilibrium in the intermediate good market therefore requires

$$(1 - \omega) y_t = \Delta_t y_t^f,$$  \hspace{1cm} (17)

where $\Delta_t \equiv \int_0^1 \left( P_t(j)/P_t \right)^{-\varepsilon} dj$ is a measure of price dispersion in final goods. Notice that price dispersion increases the amount of the intermediate good that must be produced in order to satisfy a certain level of final consumption demand.

Equilibrium in the real estate market requires

$$\bar{h} = \omega h_t + (1 - \omega) h_t^e,$$  \hspace{1cm} (18)

where $\bar{h}$ is the fixed aggregate stock of real estate. The labor market equilibrium condition is

$$\omega l^s_t = (1 - \omega) l^f_t.$$  \hspace{1cm} (19)

2.6 Fiscal and monetary authorities

The fiscal authority passively rebates its flow surplus to households in a lump-sum manner (if such surplus is negative, then it represents a lump-sum tax). Letting $s_t$ denote the surplus per household, the aggregate fiscal surplus equals

$$\omega s_t = \tau^h \omega p_t^h h_t + \tau^e (1 - \omega) \left( p_t^f y_t - w_t l_t^e \right) - \tau \int_0^1 P_t(j)y_t^f(j) dj.$$  

The model is closed by means of a monetary policy rule. The latter can be a simple rule, such as strict inflation targeting, or a policy that is optimal with respect to some criterion. Sections 4 and 5 below are devoted to characterizing different types of policy rules and their effects on equilibrium allocations.
3 Efficient equilibrium

In this section we analyze the efficient equilibrium in our model, which will be the normative benchmark for the monetary authority. We assume that, when maximizing aggregate welfare, the social planner assigns to entrepreneurs the same discount factor as that of households, $\beta$.

The social planner therefore maximizes

$$E_0 \sum_{t=0}^{\infty} \beta^t \left\{ \omega \left[ \log(c_t) - \frac{(l^*_t)^{1+\varphi}}{1+\varphi} + \vartheta_t \log(h_t) \right] + (1 - \omega) \log(c^*_t) \right\}$$

subject to the aggregate resource constraints for real estate, equation (18), and for consumption goods,

$$(1 - \omega) e^{\alpha_l} (h^*_{t-1})^\nu \left( \frac{\omega}{1-\omega} l^*_t \right)^{1-\nu} = \omega c_t + (1 - \omega) c^*_t,$$

where we have used equation (19) to substitute for $l^*_t$ in the production function. Using equations (20) and (18) to solve for $c_t$ and $h_t$, respectively, the social-planner problem simplifies to the choice of the optimal state-contingent path of $c^*_t$, $h^*_t$ and $l^*_t$. The first-order conditions of this problem can be expressed as

$$c_t = c^*_t,$$

$$\beta E_t \frac{1}{c_{t+1}^\nu} e^{\alpha_{l_{t+1}}} (h^*_{t+1})^\nu \left[ \omega l^*_{t+1} / (1 - \omega) \right]^{1-\nu} = \vartheta_t / h_t,$$

$$c_t (l^*_t)^\varphi = \frac{1 - \omega}{\omega} (1 - \nu) y_t l^*_t.$$  

Notice that equations (20) and (21) jointly imply $c_t = (1 - \omega) e^{\alpha_l} (h^*_{t-1})^\nu \left[ \omega l^*_t / (1 - \omega) \right]^{1-\nu}$. Using this in equation (22), we have that the efficient distribution of the stock of real estate is given by

$$\frac{h^*_t}{h_t} = \frac{\beta \nu}{(1 - \omega) \vartheta_t}.$$  

This, combined with equation (18), implies the following solution for aggregate housing,

$$\omega h_t = \frac{\omega \vartheta_t}{\omega \vartheta_t + \beta \nu} \bar{h}.$$  

\textsuperscript{9}Otherwise, the social planner equilibrium would assign less and less consumption to the impatient consumers (entrepreneurs) relative to the patient ones (households) as time went by. This would make the equilibrium allocation dependent on the time elapsed since the implementation of the social planner allocation. The resulting system of equations would not have a recursive representation, thus making standard solution techniques inapplicable.
Using equations (20) and (21) in equation (23) we obtain the following solution for efficient labor supply, 

\[ l_t^* = \left( \frac{1 - \nu}{\omega} \right)^{1/(1+\nu)} \equiv l^s.*. \]  

(26)

The efficient level of output is then given by

\[ y_t = e^{a_t} (h_{t-1}^e)^{\nu} \left( \frac{\omega}{1 - \omega} l^s.* \right)^{1-\nu} \equiv y_t^*. \]

(27)

To summarize, the efficient equilibrium is characterized by full consumption risk sharing between households and entrepreneurs (equation 21), a distribution of real estate that changes only with shocks to preferences for housing (equation 24) and a constant level of labor supply (equation 26).\textsuperscript{10} These features will help us understand the stabilization goals and trade-offs of monetary policy. We turn to this now.

4 Optimal monetary policy

In order to analyze optimal monetary policy, we follow the welfare-based linear-quadratic approach pioneered by Rotemberg and Woodford (1997). This method consists of deriving a log-quadratic approximation of aggregate welfare (which represents the objective function of the central bank) and a log-linear approximation of the equilibrium conditions (which are the constraints on the central bank’s optimization problem). As is well known, this method is helpful at clarifying the stabilization goals faced by the central bank and the various trade-offs among those goals. Indeed, the application of this method in our setup delivers a set of analytical results that facilitate greatly the interpretation of the subsequent numerical results.

4.1 Quadratic loss function

As emphasized by Benigno and Woodford (2008), the approximation of the aggregate welfare criterion must be purely quadratic in order for the linear-quadratic approach to provide a correct welfare ranking (with an accuracy of up to second order) of alternative monetary policy rules. Derivation of a purely quadratic approximation is greatly simplified by the assumption of an efficient steady state for the welfare-relevant variables. As shown in the Appendix, steady-state

\textsuperscript{10}The fact that neither labor hours nor the distribution of real estate are affected by productivity shocks in the efficient equilibrium is due to our assumption of logarithmic utility of consumption. Deviating from the latter assumption would complicate the algebra without adding much to our main insights about the nature of optimal monetary policy.
efficiency for such variables can be implemented in our framework by making the following three assumptions.

**Assumption 1** The subsidy rate on the revenue of final goods producers is given by

\[ \tau = \frac{\varepsilon}{\varepsilon - 1} - 1 > 0. \]

**Assumption 2** The tax rate on entrepreneur profits is given by

\[ \tau^e = 1 - \frac{1 - \omega}{(1 - \beta^e) \nu} \frac{1 - \beta^e - m \left( \frac{1}{R^L_{ss}} - \beta^e \right)}{1 - m/R^L_{ss}}. \]

**Assumption 3** The tax rate on housing wealth is given by

\[ \tau^h = \frac{\beta}{\beta^e} \frac{1 - \beta^e - m \left( \frac{1}{R^L_{ss}} - \beta^e \right)}{1 - \tau^e} - 1 + \beta. \]

The first assumption eliminates the monopolistic distortion in final goods markets, such that steady-state real marginal costs are unity \((p^f_{ss} = 1)\). The second assumption guarantees efficient risk-sharing between households and entrepreneurs in the steady state \((c_{ss} = c^e_{ss})\). The third one implements the efficient steady-state distribution of real estate between commercial and residential uses \((h^e_{ss}/h_{ss} = \beta \nu / [(1 - \omega) \vartheta])\). Under assumptions 1 to 3, aggregate welfare can be approximated by\(^{11}\)

\[ \sum_{t=0}^{\infty} \beta^t \left\{ \omega \left[ \log c_t + \vartheta_t \log h_t - \frac{(h^*_t)^{1+\varphi}}{1 + \varphi} \right] + (1 - \omega) \log c^e_t \right\} = - \sum_{t=0}^{\infty} \beta^t L_t + t.i.p. + O^3, \]

where t.i.p. are terms independent of policy, \(O^3\) are terms of order third and higher, and

\[ L_t = \lambda_\pi \tilde{x}_t^2 + \lambda_y (\tilde{y}_t - \tilde{y}_t^*)^2 + \lambda_c (\tilde{c}_t - \tilde{c}_t^*)^2 + \lambda_h \left( \tilde{h}_t - \tilde{h}_t^* \right)^2 \] \hspace{1cm} (28)

is a purely quadratic period loss function, where hats denote log-deviations from steady state and weight coefficients are given by

\[ \lambda_\pi \equiv \frac{\varepsilon \vartheta}{(1 - \vartheta) (1 - \beta \vartheta) \nu}, \hspace{1cm} \lambda_y \equiv \frac{1 + \varphi}{1 - \nu}, \hspace{1cm} \lambda_c \equiv \omega (1 - \omega), \hspace{1cm} \lambda_h \equiv \omega \vartheta \frac{\varepsilon \vartheta + \beta \nu}{\beta \nu}. \]

\(^{11}\)See the proof in the Appendix.
The loss function illustrates the existence of four stabilization goals for the central bank. The first one is inflation. As is well known, under staggered price adjustment inflation creates inefficient price dispersion and hence a welfare loss. The second goal is the output gap, which is the difference between the actual and the efficient level of output. The latter is defined as

\[ \hat{y}_t^* \equiv a_t + \nu \hat{y}_{t-1}, \]

which is simply the log-linear version of equation (27). Nominal price rigidities produce inefficient fluctuations in output, which generates in turn inefficient fluctuations in labor hours. These first two goals are standard in the New Keynesian model.

The third and fourth goals are directly related to the existence of financial frictions in this model. The third goal is the (log) difference in per capita consumption between households and entrepreneurs, i.e. between unconstrained and constrained consumers, which we may refer to as the consumption gap. This term captures the aggregate welfare losses produced by inefficient risk sharing between households and entrepreneurs, which is in turn the result of collateral constraints on entrepreneurs. The fourth goal is the (log) difference between the actual and the efficient level of housing, or housing gap, where

\[ \hat{h}_t \equiv \frac{\beta \nu \omega \vartheta}{\rho \sigma + \beta \nu \gamma} z_t^h \]

is efficient housing (see equation 25). Notice that, given the fixed supply of real estate, an inefficient level of housing is equivalent to an inefficient distribution of real estate between residential and commercial uses. In our framework, inefficiency in the real estate distribution can arise for two reasons. First, the demand for commercial property by entrepreneurs is distorted by its role as collateral in loan agreements. Second, since households and entrepreneurs differ in their degree of impatience and their consumption, they also use different stochastic discount factors for pricing future state-contingent payoffs from housing.

### 4.2 Policy trade-offs

The second step of the linear-quadratic approach consists of log-linearizing the equilibrium conditions around the steady state. For brevity, the complete list of log-linear equations is deferred to the Appendix.  

\[ \text{Simulation results not reported here indicate that the Ramsey optimal long-run gross rate of inflation is } \pi_{ss} = 1, \text{ regardless of whether the steady state is assumed to be efficient or not. Therefore, our log-linearization is performed around a zero net inflation steady state. The reason for this result is essentially the same as the} \]
for understanding the trade-offs among stabilization goals. We start by log-linearizing and combining equations (15) and (16), which yields

$$
\hat{\pi}_t = \frac{(1 - \theta) (1 - \beta \theta)}{\theta} \hat{p}_t^l + \beta E_t \hat{\pi}_{t+1}.
$$

(30)

In order to find an expression for the real marginal cost, $\hat{p}_t^l$, we first log-linearize equations (1), (7) and (19), and combine them to get

$$
\hat{c}_t + \phi \hat{\ell}_t^r = \hat{p}_t^l + \hat{y}_t - \hat{\ell}_t^r.
$$

(31)

That is, the labor supply schedule (the marginal rate of substitution between consumption and leisure) must intersect the labor demand schedule (the marginal revenue product of labor). Second, we log-linearize the production function and solve for labor hours, obtaining

$$
\hat{\ell}_t^r = \frac{1}{1 - \nu} \left( \hat{y}_t - \hat{a}_t - \nu \hat{h}_t^c \right) = \frac{1}{1 - \nu} \left( \hat{y}_t - \hat{\ell}_t^r \right),
$$

(32)

where in the second equality we have used the definition of efficient output. Third, we log-linearize the equilibrium conditions in the final goods and intermediate good markets, equations (14) and (17) respectively, and combine them into

$$
\hat{y}_t = \omega \hat{c}_t + (1 - \omega) \hat{\ell}_t^r,
$$

(33)

where we have used the fact that $(1 - \omega) y_{ss} = c_{ss} = \hat{c}_{ss}$ and that $\hat{\Delta}_t$ is actually a second-order term (see the appendix). Combining equations (31) to (33), we can express real marginal costs as

$$
\hat{p}_t^l = \frac{1 + \phi}{1 - \nu} \left( \hat{y}_t - \hat{\ell}_t^r \right) + (1 - \omega) \left( \hat{c}_t - \hat{\ell}_t^r \right).
$$

(34)

Using this in equation (30) yields the following *New Keynesian Phillips curve*,

$$
\hat{\pi}_t = \kappa \frac{1 + \phi}{1 - \nu} \left( \hat{y}_t - \hat{\ell}_t^r \right) + \beta E_t \hat{\pi}_{t+1} + \kappa \left( 1 - \omega \right) \left( \hat{c}_t - \hat{\ell}_t^r \right),
$$

(35)

where $\kappa \equiv (1 - \theta) (1 - \beta \theta) / \theta$. Equation (35) has the same form as the standard New Keynesian Phillips curve, with the exception of the last term on the right hand side, which is proportional to the consumption gap. Therefore, collateral constraints and the resulting inefficient risk-reason why the optimal long-run net rate of inflation is zero in the standard New Keynesian model, namely that the welfare losses of committing to positive inflation rates in the future outweigh the welfare gains of exploiting the short-run output-inflation trade-off when output is inefficiently low (see e.g. Woodford, 2003, ch. 6).
sharing create an endogenous trade-off between the output gap and inflation. The reason is the following. From equation (31), real marginal costs \( \hat{p}_t \) depend on labor hours and the difference between aggregate demand and household consumption. Because of inefficient risk sharing, fluctuations in aggregate demand and household consumption will be unequal. As a result, keeping labor hours constant (that is, closing the output gap) is not enough to prevent fluctuations in real marginal costs and hence in inflation.

From the preceding analysis, it follows that closing the consumption gap has two beneficial effects on aggregate welfare. First, it improves the trade-off between inflation and output gap. Second, since the consumption gap is itself a stabilization goal, closing it directly improves welfare. An additional normative reason for closing the consumption gap is that it reduces the distortionary effects of collateral constraints on entrepreneurs’ stochastic discount factor and hence on their valuation of future income streams from commercial property. This makes the real estate distribution more efficient over the cycle and thus helps closing the housing gap.

While desirable, consumption gap stabilization requires itself inefficient fluctuations in other stabilization goals. To see this, consider the log-linear approximation of the expression for entrepreneur consumption (equation 10) around the efficient steady state,

\[
\tilde{c}_t = (1 - \beta^e) \left[ \frac{1 - \tau^e \nu}{1 - \omega} \left( \hat{p}_t^I + \hat{y}_t \right) + \frac{p^{h \epsilon}_{ss} h^{c}_{ss}}{c^e_{ss}} \left( \hat{p}_t^h + \hat{\pi}_{t-1}^c \right) - \frac{b_{ss} R_{ss}^L}{c^e_{ss}} \left( \hat{R}_{t-1}^L + \hat{b}_{t-1} - \hat{\pi}_t \right) \right],
\]

where both sides have been normalized by \( c^e_{ss} \) and the steady-state condition \( c^e_{ss}/y_{ss} = 1 - \omega \) has been used. The binding collateral constraint (equation 6 holding with equality) can be approximated by \( \hat{R}_{t}^L + \hat{b}_t = z^{m}_t + E_t \hat{p}_{t+1}^h + \hat{\pi}_t^c + E_t \hat{\pi}_{t+1} \). Substituting this into equation (36), using \( b_{ss} R_{ss}^L = m p^{h \epsilon}_{ss} h^{c}_{ss} \), and rearranging terms, we obtain

\[
\tilde{c}_t = (1 - \beta^e) \left( 1 - \tau^e \nu \right) \frac{1}{1 - \omega} \left( \hat{p}_t^I + \hat{y}_t \right) + \frac{p^{h \epsilon}_{ss} h^{c}_{ss}}{c^e_{ss}} \left[ \left( \hat{p}_t^h - m E_{t-1} \hat{p}_t^h \right) + \left( 1 - m \right) \hat{\pi}_{t-1}^c + m \left( \hat{\pi}_t - E_{t-1} \hat{\pi}_t \right) - m z^{m}_{t-1} \right].
\]

Therefore, entrepreneur profits \( \left( \hat{p}_t^I + \hat{y}_t \right) \), quasi-surprises in real estate prices \( \left( \hat{p}_t^h - m E_{t-1} \hat{p}_t^h \right) \), the stock of commercial property and inflation surprises \( \left( \hat{\pi}_t - E_{t-1} \hat{\pi}_t \right) \) are the endogenous determinants of entrepreneur consumption. The latter will therefore differ from household consumption, which is driven exclusively by intertemporal substitution considerations. In response to unexpected shocks, it is however possible for the central bank to bring entrepreneur and household consumption closer to each other. First, indirect manipulation of real estate prices through interest rate policy is an effective way for the central bank to adjust the path
of entrepreneur consumption. Second, the central bank can also engineer inflation surprises so as to alter the real value of debt repayments. Third, notice that entrepreneur profits can be expressed in terms of stabilization goals as follows,

\[ \hat{p}_t^I + \hat{y}_t = \left( \frac{1 + \varphi}{1 - \nu} + 1 \right) (\hat{y}_t - \hat{y}_t^*) + (1 - \omega) (\hat{e}_t - \hat{e}_t^*) + \hat{y}_t^*, \]

where we have used equation (34) to substitute for \( \hat{p}_t^I \). Therefore, the central bank can also resort to output-gap management in order to narrow the consumption gap.

To summarize, optimal monetary policy will involve a trade-off between all four stabilization goals in response to macroeconomic shocks. We now turn to the quantitative analysis of these trade-offs.

5 Quantitative analysis

5.1 Calibration

We calibrate our model to quarterly US data. The calibration is largely based on Andrés and Arce (2008) and Iacoviello (2005). The household discount factor, \( \beta = 0.993 \), is chosen such that the annual real interest rate equals 3%. The entrepreneur discount factor is set to 0.95, within the range of values for constrained consumers typically used in the literature. The elasticity of production with respect to commercial housing, \( \nu \), is set to generate a steady-state ratio of commercial real estate wealth to annual output of 62%. Similarly, the weight on housing utility, \( \vartheta \), is chosen to match an average ratio of housing wealth to annual output of 140%. Regarding the banking parameters, what matters for the steady-state level of lending spreads is the ratio \( n/\alpha \). We arbitrarily set the number of banks to 10, and then set the distance utility parameter, \( \alpha \), to obtain a steady-state annualized lending spread of 2.5%. The size of the household population, \( \omega = 0.979 \), is chosen such that the tax rate on entrepreneur profits that implements the efficient steady state is zero.\(^{13}\) The loan-to-value ratio is set to \( m = 0.85 \), as in Iacoviello (2005). The labor supply elasticity is set to one half, which is broadly consistent with micro evidence. The elasticity of demand curves is set to 6, which would imply a monopolistic mark-up of 20% in the absence of subsidies. The Calvo parameter implies a mean duration of price contracts of 3 quarters, consistent with recent micro evidence (Bils and Klenow, 2004,

\(^{13}\)Alternatively, we could have calibrated \( \omega \) empirically and then obtained \( \tau^c \) from the formula in section 4.1 . Since the share of entrepreneurs in the population is fairly small, this alternative approach would produce a very similar calibration.
Nakamura and Steinsson, 2008). The tax rate on housing wealth that implements the efficient steady state is \( \tau^h = 0.012 \). The structural parameters imply weights (normalized by their sum) of \( \lambda_r = 91.2\% \), \( \lambda_y = 7.9\% \), \( \lambda_c = 0.1\% \) and \( \lambda_h = 0.8\% \) in the loss function. Finally, the autocorrelation coefficient of \( a_t \) is set to a standard value of 0.95, whereas that of \( z_t^m \) is set to 0.75, implying a half-life of four quarters for shocks to the pledgeability ratio.

5.2 Impulse-response analysis

In order to further investigate the nature of optimal monetary policy in this framework, we now analyze the economy’s response to shocks under the optimal commitment. We consider both productivity shocks as well as credit-crunch shocks, the latter in the form of shocks to the pledgeability ratio.\(^{14}\) We also analyze the impulse-responses under a policy of strict inflation targeting (\( \hat{\pi}_t = 0 \)). Such a policy has been shown to be optimal in the standard New Keynesian model (see e.g. Goodfriend and King, 2001, and Woodford, 2003). By comparing both policies, we can illustrate the trade-offs that render inflation targeting suboptimal in this framework.

5.2.1 Productivity shocks

Figure 1 plots the economy’s response to a 1% negative productivity shock. Let us focus first on the case of strict inflation targeting (dotted lines). The fall in total factor productivity reduces the marginal product of commercial real estate. Entrepreneurs respond by reducing

\(^{14}\)For brevity, we omit the results regarding the effects of shocks to the utility of housing services (\( \vartheta_t \)). These results are available upon request from the authors.
their demand for property, which leads to a persistent decline in real estate prices. Lower expected asset prices means that real estate is less valuable as a collateral, which further reduces demand for commercial real estate. Since productivity shocks do not affect the efficient real estate distribution, the fall in commercial property is mirrored by a symmetric increase in the housing gap. Also, lower profits and lower real estate wealth trigger a large reduction in entrepreneur net worth and therefore in entrepreneur consumption. Household consumption falls too, but it does so by a relatively small amount, thanks to households’ better ability to smooth consumption. As a result, the consumption gap increases sharply on impact. In addition to lowering welfare directly, the consumption gap also shifts the New Keynesian Phillips curve upwards. In order to keep inflation at zero, the central bank is obliged to engineer a (small) drop in the output gap. To summarize, strict inflation targeting requires inefficient fluctuations in the output gap and, especially, in the consumption and housing gaps.

**Figure 1: Impulse-responses to a negative productivity shock**

Relative to the situation under inflation targeting, the optimal policy (solid line) can improve matters by cutting the nominal interest rate more sharply on impact. This way, it undoes part of
the reduction in entrepreneurs’ demand for commercial real estate, thus narrowing the housing gap. Thanks to the smaller drop in real estate prices and in commercial property, entrepreneurs’ net worth and consumption fall substantially less, which produces a significant reduction in the consumption gap. Notice that the more aggressive policy response leads to an increase in the output gap and inflation on impact. This lowers welfare directly, but it also helps at reducing the consumption gap, by increasing entrepreneur profits and reducing their real debt burden. Calculations not reported here show however that most of the reduction in the consumption gap is due to the smaller drop in real estate prices. The contraction in the consumption gap contains the upward shift in the New Keynesian Phillips curve, thus improving the trade-off between inflation and output gap. Indeed, both variables return to zero very quickly. Finally, the endogenous response in lending spreads (not shown in the figure) is very small under both policy regimes, with peak drops of 1 and 0.2 basis points, respectively. This suggests that, under our baseline calibration, the endogenous fluctuations in lending margins do not seem to alter the effects of productivity shocks in a quantitatively important way.15

5.2.2 Credit crunch shocks

Figure 2 plots the impulse-responses to a 1% negative shock to the pledgeability ratio. Again, we focus first on the case of inflation targeting (dotted lines). The fall in the pledgeability ratio reduces the marginal value of commercial real estate by reducing its value as collateral. Entrepreneurs respond by decreasing their demand for commercial real estate. This produces again a symmetric increase in the housing gap, because the efficient real estate distribution is independent of the pledgeability ratio. Regarding the other stabilization goals, the responses are of minor importance. First, the absolute deviations of the consumption gap from its efficient value (zero) are much smaller than in the case of a productivity shock. The reason is that the credit crunch has two opposing effects on entrepreneur net worth. On the one hand, the fall in the price and the quantity of real estate reduces entrepreneurial net worth but, on the other hand, the credit crunch lowers their real debt burden in subsequent periods, thus improving their net worth. As the center right panel shows, the latter effect becomes dominant from the third period onwards. Second, since what matters for inflation dynamics is the present-discounted sum of consumption gaps and the latter sum responds relatively little, the shift in the New Keynesian Phillips curve is small, such that a tiny correction in the output gap is enough to keep inflation at zero.

---

15 Andrés and Arce (2008) provide a detailed analysis of the various opposite-sign effects that explain such a low responsiveness of spreads following a productivity shock.
Therefore, the optimal policy (solid lines) is primarily aimed at reducing the housing gap. In order to achieve this, the monetary authority resorts again to a sharper reduction in the policy rate. This way, it counteracts the negative effect of the credit crunch on entrepreneurs’ demand for commercial property. As in the case of productivity shocks, this policy comes at the cost of increases in inflation and the output gap on impact, followed by transitory negative deviations from their efficient levels (zero). Notice finally that lending margins experience a non-negligible impact increase of 15 basis points in annualized terms (lower left panel), which contrasts with their negligible response to productivity shocks. This is due to the fact that lending margins depend negatively on the pledgeability ratio, through the latter’s effect on the elasticity of demand for funding. This countercyclical response of lending margins has the property of amplifying the negative effect of the credit crunch under both policy scenarios.

5.3 Welfare analysis

The previous section characterized the responses of the stabilization goals to productivity and credit-crunch shocks. These goals however enter with different weights in the loss function of
the central bank, and therefore have different quantitative effects on welfare. We are ultimately concerned with the welfare implications of alternative monetary policy rules. This subsection quantifies the welfare losses that arise under different such rules.

5.3.1 Welfare losses under the baseline calibration

The first four columns of Table 2 display the standard deviation of the four stabilization goals, conditional on productivity shocks (with a standard deviation of 1%). As in the analysis of impulse responses, we consider the cases of inflation targeting and the optimal policy commitment. We also include output gap targeting ($y_t = \bar{y}_t^*$), which is equivalent to inflation targeting in the standard New Keynesian model (in the absence of an exogenous output-inflation trade-off) but not in our framework, due to the presence of the consumption gap in the New Keynesian Phillips curve. The last column displays the implied average welfare loss, as a percent of steady-state consumption.

Note: standard deviations in %, welfare loss as a % of steady-state consumption

** optimal weight: $\zeta = 0.212$

As the table makes clear, a policy of strict inflation targeting implies large fluctuations in the consumption and housing gaps. Fluctuations in the output gap are rather small. These volatilities, together with the weights in the loss function, imply an average welfare loss of 0.11% of steady-state consumption. Regarding the case of output gap targeting, fluctuations in the consumption and housing gaps are of similar magnitude, whereas (annualized) inflation has a standard deviation of 85 basis points. The implied average welfare loss (0.09%) is close to the one under inflation targeting. Finally, the optimal monetary policy balances all the trade-offs among goals, producing a welfare loss of just 0.03% of steady-state consumption.

Table 3 shows the standard deviation of the stabilization goals and the implied average welfare losses, conditional on shocks to the pledgeability ratio (with a standard deviation of
1%). Again, the larger fluctuations take place in the consumption and housing gaps. Under inflation and output-gap targeting, housing gaps are more volatile than consumption gaps. Since the former have a larger weight in the loss function, the optimal policy focuses on reducing fluctuations in the housing gap. This comes at the cost of larger fluctuations in all other goals. Intuitively, exogenous changes in the pledgeability ratio directly affect both the value of real estate as collateral and the lending margins charged to entrepreneurs; as a result, the policy of sustaining demand for commercial real estate becomes less effective and hence more costly in terms of the other goals. This implies that, in terms of average welfare losses, inflation and output-gap targeting are much closer to the optimal policy than in the case of productivity shocks.

** optimal weight: $\zeta = 0.262$

Optimal simple targeting rules. In the standard New Keynesian model without an exogenous trade-off between inflation and output (the so-called "cost-push" shocks), the targeting rule that implements the optimal monetary policy commitment is simply $\dot{\pi}_t = 0$. In the presence of cost-push shocks, the corresponding targeting rule is a simple and intuitive expression linking inflation and the output gap (see e.g. Woodford 2003, ch. 7). In our model, due to the presence of financial frictions, the optimal targeting rule is too complex to be implemented in practice. In order to make the optimal monetary policy in our framework operational, we look for a simple targeting rule based only on observables that approximates well the optimal policy. The impulse responses in Figures 1 and 2 offer a guidance for the choice of such a rule. These figures suggest that real estate prices play a key role in the implementation of the optimal policy commitment. This is particularly true in the case of productivity shocks, where manipulation of real estate prices by the central bank is particularly effective at smoothing the
consumption gap. For this reason, we consider the following family of simple targeting rules,

$$\hat{p}_t + \zeta \left( \hat{p}_t^h - \hat{p}_{t-1}^h + E_t \hat{p}_{t+1}^h - \hat{p}_t^h \right) = 0.$$  

According to this rule, the central bank targets a weighted average of inflation, on the one hand, and the arithmetic mean of the current and the expected growth rate in the real price of real estate, on the other.\textsuperscript{16} In the special case of $\zeta = 0$, the rule collapses to strict inflation targeting. For each shock, we find the value of $\zeta$ that minimizes the average welfare loss. The last line of tables 2 and 3 display the results under our proposed rule, which is labelled as ‘simple targeting rule’. In the case of productivity shocks (table 2), our simple rule is very close to the optimal in terms of welfare loss. Indeed, the rule succeeds in reducing the volatility of both the consumption and housing gaps, relative to the other two suboptimal policies. Conditional on credit crunch shocks (table 3), welfare losses under our simple rule are very similar to (though not higher than) those under the other suboptimal rules, although this is not surprising given the small differences between the latter and the optimal policy. The simple rule does share with the optimal policy the feature of reducing the volatility of the housing gap while increasing fluctuations in the other goals. Interestingly, the optimal value of the weight coefficient, $\zeta$, is very similar for both shocks, which guarantees that the same rule with a similar coefficient performs well also unconditionally.\textsuperscript{17}

5.3.2 The effects of banking competition

The welfare analysis can also shed some light on the importance of the intensity of competition in the banking sector.\textsuperscript{18} To isolate the effects of banking competition on the previous monetary policy trade-offs, we repeat our exercises under the assumption of perfect banking competition ($\alpha = 0$, or $n \to \infty$). In the latter scenario, the steady-state loan rate, $R_{ss}^L$, falls from its baseline

\textsuperscript{16}We also considered a policy that set to zero the weights on the consumption and housing gaps in the quadratic loss function, and minimized the resulting ‘myopic’ loss function. Although such a policy does not deliver a simple expression for the targeting rule either, it can shed light on the extent to which monetary policy should worry about the non-standard stabilization goals. We found that such a policy was much closer to inflation or output gap targeting than to the optimal policy in terms of welfare loss. This strongly suggests that the central bank should not obviate the goals arising from financial frictions in the conduct of monetary policy.

\textsuperscript{17}Indeed, once both shocks are taken into account (with an equal standard deviation of 1%), we find an optimal weight coefficient of $\zeta = 0.214$. Welfare losses in this case equal 0.08% of steady-state consumption, which is close to those under the optimal policy (0.06%) and substantially lower than those under inflation or output gap targeting (0.15% and 0.14%, respectively).

\textsuperscript{18}Andrés and Arce (2008) find that variations in the level of banking competition have a moderate effect on the short term impulse response dynamics of the main variables, but a sizeable one in the medium term, due to the interaction between lending spreads and persistent net worth effects.
value to $R^D_{ss} = 1/\beta$, and the interest rate spread becomes zero. The effect of this structural change on the fluctuations of the stabilization goals and the associated welfare losses, conditional on productivity shocks, is summarized in Table 4.

Note: standard deviations in %, welfare loss as a % of steady-state consumption

**optimal weights: $\zeta = 0.212$ (baseline) and $\zeta = 0.251$ (perfect competition)

As the table makes clear, the policy trade-offs worsen when the banking industry is more competitive. For both inflation and output-gap targeting, all stabilization goals other than the one being targeted become more volatile. As a result, average welfare losses increase. Regarding the optimal policy, the increase in inflation and output-gap volatility is partially offset by smaller fluctuations in the consumption and housing gaps. However, the large weights of the former two goals in the loss function (91.2% and 7.9%, respectively) imply an increase in average welfare loss. This increase is however small. The same can be said about the simple targeting rule based on inflation and real estate prices, which remains very close to the optimal policy in terms of welfare loss. We conclude that, conditional on productivity shocks, the transit to perfect banking competition makes the policy trade-offs more severe, but especially so for the suboptimal policy rules.
To understand these results, it is helpful to consider the steady-state effects of an increase in banking competition. We start by defining the leverage ratio as the fraction of borrowers’ asset holdings that are financed with debt, $b_i / (p_i^b h^e_i)$. Binding collateral constraints imply that, in the steady state, the leverage ratio equals $b_{ss} / (p_{ss}^b h_{ss}^e) = m/R_{ss}^L$. Therefore, the fall in loan rates produced by stronger banking competition increases the steady-state leverage ratio. Now consider equation (37), which determines the cyclical fluctuations in entrepreneur consumption. In the latter equation, the term capturing the sensitivity of entrepreneur consumption to real estate prices can be expressed as

$$(1 - \beta^e) \frac{p_{ss}^b h_{ss}^e}{c_{ss}^e} = \frac{\beta^e}{1 - b_{ss} / (p_{ss}^b h_{ss}^e)},$$

where we have used the fact that $c_{ss}^e = (1 - \beta^e) \left( p_{ss}^b h_{ss}^e - b_{ss} \right) / \beta^e$, which in turn stems from the fact that entrepreneurs devote a fraction $1 - \beta^e$ of their real net worth to consumption, $c_{ss}^e$, and the remaining fraction $\beta^e$ to financing the part of real estate holdings that exceeds the amount of borrowing, $p_{ss}^b h_{ss}^e - b_{ss}$. Therefore, the increase in the steady-state leverage ratio amplifies the effect of fluctuations in real estate prices on entrepreneur consumption. Since household consumption is not affected by collateral constraints, the increased volatility of entrepreneur consumption carries over to the consumption gap. As we have seen, this has a direct negative effect on welfare, but it also worsens the output-inflation trade-off (by causing larger shifts in the Phillips curve) and amplifies the distortions in the distribution of real estate through its effects on entrepreneurs’ stochastic discount factor. Taking all these effects together, we have that the increase in banking competition tends to exacerbate the trade-offs of monetary policy and the associated welfare losses.

Table 5 shows the effects of stronger banking competition on welfare losses conditional on credit-crunch shocks. The main message from the table is that the volatility of the different stabilization goals tends to increase but it does so by very small amounts, and in some cases such volatilities actually fall. As a result, the effect on average welfare losses is virtually inexistent. The intuition for this can be found in the behavior of the lending spread. The latter responds countercyclically to credit crunch shocks when banks have market power, thus amplifying the effects on the economy. However, under perfect banking competition lending spreads are zero, and so their amplifying role disappears. As the table makes clear, this basically neutralizes the amplifying effect of the leverage ratio on welfare losses.

6 Conclusions

In this paper we provide a theoretical framework for the analysis of the optimal conduct of monetary policy in the presence of financial frictions, in the form of collateral constraints and a monopolistically competitive banking sector. In our economy consumers are divided into households and entrepreneurs, with different time preferences. The resulting credit flows are intermediated by banks, which have some monopolistic power in the loans market and set optimal lending rates accordingly. There is only one collateralizable asset, real estate, which also yields utility to households and productive returns to entrepreneurs. The latter face endogenous credit limits that link their borrowing capacity to the expected value of their real estate holdings.

We have shown that, under the assumption of steady state efficiency in the welfare-relevant variables and up to a second order approximation, welfare maximization is equivalent to stabilization of four goals: inflation, output gap, the consumption gap between households and entrepreneurs, and the distribution of real estate between both groups (or housing gap). Follow-
ing both productivity and credit-crunch shocks (the latter in the form of exogenous changes in collateral requirements), the optimal monetary policy commitment implies a short-run trade-off between stabilization goals. Relative to strict inflation targeting, the optimal policy commitment changes the nominal policy rate more aggressively so as to avoid large fluctuations in the consumption and housing gaps. This policy comes at the cost of inefficient fluctuations in inflation and the output gap. The welfare gain of pursuing optimal policies is comparatively larger under productivity-driven fluctuations. Credit-crunch shocks have a direct effect both on lending margins and on the collateral value of real estate, such that policies aimed at sustaining entrepreneurs’ demand for real estate (and hence at preventing the emergence of large housing gaps) become less effective.

We also compare the nature of these trade-offs under alternative assumptions about the degree of competition in the banking industry. We find that, both under optimal and suboptimal policies, welfare losses due to cyclical fluctuations are amplified as banking competition increases. This amplification is negligible in financially driven (credit-crunch) fluctuations, but is substantial if productivity shocks dominate. Key to these results is the interplay between two endogenous mechanisms at work in our model: financial leveraging and lending margins. As banking competition increases, entrepreneurs become more leveraged and this amplifies the response of their net worth (and hence their consumption). This latter feature worsens the aforementioned trade-offs, especially under suboptimal policy rules, thus making the use of the optimal policy more compelling. The countercyclical response of lending margins, which is naturally stronger in less competitive environments, aggravates the policy trade-offs. The first mechanism is equally important regardless of the nature of the shocks, whereas the second one is very weak under productivity shocks and significant if credit-crunch shocks are the driving force behind fluctuations.
References

7 Appendix

7.1 The entrepreneur’s consumption decision

Equations (8) and (9) in the text can be combined as follows,

\[
p_t^h - \chi_t \frac{c_t^e}{c_t} = \beta^e E_t \left\{ \frac{(1 - \tau^e) \nu p_{t+1}^d y_{t+1}/h_t^e + p_t^b - R_t^L \chi_t/\pi_{t+1}}{c_{t+1}} \right\},
\]

(38)

where \( \chi_t \equiv m_t E_t \pi_{t+1} p_t^h / R_t^L \). The latter definition allows us in turn to write the collateral constraint (equation 6) as

\[
b_t = \chi_t h_t^e.
\]

(39)

Define real net worth, \( n w_t \), as the sum of after-tax real profits and beginning-of-period real estate wealth, minus real debt repayments,

\[
n w_t \equiv (1 - \tau^e) \left( p_t^I y_t - w_t p_t^d \right) + p_t^b h_t^e - \frac{R_t^L}{\pi_t} b_{t-1}
\]

\[= (1 - \tau^e) \nu p_t^I y_t + p_t^b h_t^e - \frac{R_t^L}{\pi_t} \chi_{t-1} h_{t-1}^e
\]

\[= \left[ (1 - \tau^e) \nu p_t^I y_t / h_{t-1}^e + p_t^b - \frac{R_t^L}{\pi_t} \chi_{t-1} \right] h_{t-1}^e,
\]

(40)

where in the first equality we have used (7) to substitute for \( w_t p_t^d \) and (39) to substitute for \( b_{t-1} \). We now guess that the entrepreneur consumes a fraction \( 1 - \beta^e \) of her real net worth,

\[
c_t^e = (1 - \beta^e) n w_t.
\]

(41)

Using (40) and (41) in equation (38), the latter collapses to

\[
\frac{p_t^h - \chi_t}{c_t^e} = \beta^e \frac{1}{1 - \beta^e h_t^e}.
\]

(42)

At the same time, the definition of real net worth and equation (39) allow us write the entrepreneur’s budget constraint (equation 5) as

\[
\chi_t h_t^e + n w_t = c_t^e + p_t^b h_t^e.
\]

Combining the latter with equation (42), we finally obtain equation (41), which verifies our guess.
7.2 Implementation of the efficient steady state

Equations (1), (7) and (19) in the steady state jointly imply

\[ c_{ss} \left( l_{ss}^s \right)^{\varphi} = \frac{1 - \omega}{\omega} (1 - \nu) p_{ss}^I \frac{y_{ss}^e}{l_{ss}^s}. \]

The latter corresponds to its efficient counterpart (the steady state of equation 23) only if \( p_{ss}^I = 1 \). In the steady state, equation (15) becomes \( 1 + \tau = \left[ \varepsilon / (\varepsilon - 1) \right] p_{ss}^I \), where \( \tau \) is the subsidy rate on the revenue of final goods producers. Therefore, steady-state efficiency requires setting the subsidy rate to

\[ \tau = \frac{\varepsilon}{\varepsilon - 1} - 1. \]

On the other hand, the steady-state counterpart of equation (10), rescaled by \( y_{ss} \), is given by

\[ \frac{c_{ss}^e}{y_{ss}} = (1 - \beta^e) \left[ (1 - \tau^e) \nu + (1 - m) \frac{p_{ss}^h h_{ss}^e}{y_{ss}} \right], \tag{43} \]

where we have imposed \( p_{ss}^I = 1 \) and we have also used the steady-state collateral constraint, \( R_{ss}^L b_{ss} = m p_{ss}^h h_{ss}^e \). Similarly, the steady-state counterparts of equations (9) and (8) jointly imply

\[ \frac{p_{ss}^h h_{ss}^e}{y_{ss}} = \beta^e \left[ (1 - \tau^e) \nu + \frac{p_{ss}^h h_{ss}^e}{y_{ss}} \right] + \frac{1}{R_{ss}^L - \beta^e} m \frac{p_{ss}^h h_{ss}^e}{y_{ss}}, \]

which implies the following steady-state ratio of entrepreneurial real estate wealth over output,

\[ \frac{p_{ss}^h h_{ss}^e}{y_{ss}} = \frac{\beta^e (1 - \tau^e) \nu}{1 - \beta^e - m (1/R_{ss}^L - \beta^e)}. \tag{44} \]

Using (44) to substitute for \( p_{ss}^h h_{ss}^e/y_{ss}^e \) in (43), and imposing the steady-state efficiency requirement that \( c_{ss}^e/y_{ss} = 1 - \omega \) (as a result of \( c_{ss} = c_{ss}^e \) and \( [1 - \omega] y_{ss} = \omega c_{ss} + [1 - \omega] c_{ss}^e \)), we can solve for the tax rate that implements an efficient allocation in the steady state,

\[ \tau^e = 1 - \frac{1 - \omega}{(1 - \beta^e) \nu} \frac{1 - \beta^e - m (1/R_{ss}^L - \beta^e)}{1 - m/R_{ss}^L}. \]

Finally, equation (3) implies that, in the steady state,

\[ \frac{p_{ss}^h h_{ss}}{c_{ss}} = \frac{\vartheta}{1 - \beta + \tau^h}. \]
Combining this with equation (44) and the efficiency requirement $c_{ss} = e_{ss} = (1 - \omega) y_{ss}$, we have that the steady-state distribution of real estate in the decentralized economy is given by

$$ h_{ss}^e = \frac{(1 - \omega) \vartheta}{\beta^e (1 - \tau^e) \nu} \frac{1 - \beta^e - m \left(1/R^L_{ss} - \beta^e\right)}{1 - \beta + \tau^h}. $$

The latter coincides with the efficient steady-state distribution, $(1 - \omega) \vartheta / (\beta \nu)$, only if

$$ \tau^h = \frac{\beta}{\beta^e} \frac{1 - \beta^e - m \left(1/R^L_{ss} - \beta^e\right)}{1 - \tau^e} - (1 - \beta). $$

### 7.3 Derivation of the quadratic loss function

We start by performing a second order approximation (in logs) of the period utility function around the steady-state,

$$ U_t = \omega \left[ \log(c_t) + \vartheta_t \log(h_t) - \frac{(l_t^h)^{1+\varphi}}{1+\varphi} \right] + (1 - \omega) \log(e_t^h) $$

$$ = \omega \hat{c}_t + (1 - \omega) \hat{c}_t^e - \omega \left(l_{ss}^h\right)^{1+\varphi} \left(\hat{l}_t + \frac{1+\varphi}{2} \hat{l}_t^2\right) + \omega \vartheta \left(\hat{h}_t + z_t^h \hat{h}_t\right) + t.i.p. + O^3, \quad (45) $$

where hats denote log-deviations from steady state, the subscript $ss$ indicates steady state values, $t.i.p.$ are terms independent of policy and $O^3$ collects all terms of order third and higher in the size of the shocks.

The aggregate resource constraint in goods markets, $(1 - \omega) y_t/\Delta_t = \omega c_t + (1 - \omega) c_t^e$, can be approximated by

$$ (1 - \omega) \left(\frac{1}{2} \hat{y}_t^2 - \hat{\Delta}_t\right) = \omega \frac{c_{ss}}{y_{ss}} \left(\hat{c}_t + \frac{1}{2} \hat{c}_t^2\right) + (1 - \omega) \frac{e_{ss}}{y_{ss}} \left(\hat{c}_t^e + \frac{1}{2} (\hat{c}_t^e)^2\right) + O^3, \quad (46) $$

where we have used the fact that $\hat{\Delta}_t$ is already a second-order term (see below). Equation (46) implies that

$$ \hat{y}_t^2 = \left(\frac{\omega c_{ss}}{1 - \omega y_{ss}}\right)^2 \hat{c}_t^2 + \left(\frac{e_{ss}}{y_{ss}}\right)^2 (\hat{c}_t^e)^2 + 2 \frac{\omega c_{ss}}{1 - \omega y_{ss}} \frac{e_{ss}}{y_{ss}} \hat{c}_t \hat{c}_t^e + O^3. $$
\[
\ddot{y}_t = \frac{\omega}{1 - \omega} \frac{c_{ss}}{y_{ss}} \ddot{c}_t + \frac{c_{ss}^e}{y_{ss}} \dddot{c}_t + \Delta_t + O^3
\]
\[
+ \frac{1}{2} \left[ \frac{\omega}{1 - \omega} \frac{c_{ss}}{y_{ss}} \left( 1 - \frac{\omega}{1 - \omega} \frac{c_{ss}}{y_{ss}} \right) \dddot{c}_t^2 + \frac{c_{ss}^e}{y_{ss}} \left( 1 - \frac{c_{ss}^e}{y_{ss}} \right) (\dddot{c}_t)^2 - \frac{\omega}{1 - \omega} \frac{c_{ss} c_{ss}^e}{y_{ss}} \dddot{c}_t \dddot{c}_t^e \right]. \tag{47}
\]

We now make use of our assumption of efficient steady state. This implies \( c_{ss} = c_{ss}^e = (1 - \omega) y_{ss} \). Using this in (47) yields
\[
\dot{y}_t = \omega \ddot{c}_t + (1 - \omega) \dddot{c}_t^e + \Delta_t + \frac{\omega (1 - \omega)}{2} (\dddot{c}_t^e)^2 + O^3. \tag{48}
\]

The production function, \( y_t = e^{\alpha t} \left( \omega l_t^s / (1 - \omega) \right)^{1-\nu} (h_{t-1}^e)^{\nu} \), admits the following exact log-linear representation,
\[
\dot{y}_t = a_t + (1 - \nu) \ddot{h}_t^e + \nu \dot{h}_t^e. \tag{49}
\]

Using (48) and (49) to substitute for \( \omega \ddot{c}_t + (1 - \omega) \dddot{c}_t^e \) and \( \dot{h}_t^e \) respectively in (45), we obtain
\[
U_t = \dot{y}_t - \Delta_t - \omega (l_{ss}^s)^{1+\varphi} \left[ \frac{\dot{y}_t - \nu \dot{h}_{t-1}^e}{1 - \nu} + \frac{1 + \varphi}{2} \left( \frac{\dot{y}_t - a_t - \nu \dot{h}_{t-1}^e}{1 - \nu} \right)^2 \right]
\]
\[
- \frac{\omega (1 - \omega)}{2} (\dddot{c}_t^e)^2 + \omega \ddot{h}_t^e \left( \hat{h}_t + z_t^h \hat{h}_t \right) + t.i.p. + O^3. \tag{50}
\]

In an efficient steady state, labor market equilibrium implies \( c_{ss} (l_{ss}^s)^{1+\varphi} = (1 - \nu) y_{ss}^s / \left( \frac{\omega}{1 - \omega} l_{ss}^s \right) \), which combined with \( c_{ss} = (1 - \omega) y_{ss} \) implies \( \omega (l_{ss}^s)^{1+\varphi} = 1 - \nu \). Using this in (50), we have
\[
U_t = \nu \dot{h}_{t-1} + \omega \vartheta \left( \hat{h}_t + z_t^h \hat{h}_t \right) - \frac{1 + \varphi}{2} (\dot{y}_t - \dot{y}_t^e)^2 - \frac{\omega (1 - \omega)}{2} (\dddot{c}_t^e)^2 - \Delta_t + t.i.p. + O^3, \tag{51}
\]

where we have used the definition of efficient output (in log-deviations), \( \ddot{y}_t^e = a_t + \nu \dot{h}_{t-1}^e \). Taking the present discount sum of (51), we have
\[
\sum_{t=0}^{\infty} \beta^t U_t = - \frac{1}{2} \sum_{t=0}^{\infty} \beta^t \left[ \frac{1 + \varphi}{1 - \nu} (\dot{y}_t - \dot{y}_t^e)^2 + \omega (1 - \omega) (\dddot{c}_t^e)^2 \right]
\]
\[
+ \sum_{t=0}^{\infty} \beta^t \left[ \beta \nu \dot{h}_t + \omega \vartheta (\hat{h}_t + z_t^h \hat{h}_t) \right] - \sum_{t=0}^{\infty} \beta^t \Delta_t + t.i.p. + O^3, \tag{52}
\]

where we have used the fact that \( \dot{h}_{t-1}^e \) and \( \Delta_{t-1} \) are independent of policy as of time 0. The
equilibrium condition in the real estate market, $\bar{h} = \omega h_t + (1 - \omega) h_{t}^e$, can be approximated as follows,

$$\omega h_{ss} \left( \hat{h}_t + \frac{\hat{h}_{t}^2}{2} \right) + (1 - \omega) h_{ss}^e \left( \hat{h}_{t}^e + \frac{\left( \hat{h}_{t}^e \right)^2}{2} \right) = O^3. \tag{53}$$

The latter equation implies that $\left( \hat{h}_{t}^e \right)^2 = \left[ \omega / (1 - \omega) \right]^2 \left( h_{ss} / h_{ss}^e \right)^2 \hat{h}_{t}^2 + O^3$. Using this and the efficient distribution of real estate in the steady state, $h_{ss} / h_{ss}^e = (1 - \omega) \vartheta / (\beta \nu)$, equation (53) becomes

$$\omega \vartheta \hat{h}_t + \beta \nu \hat{h}_t^e = -\frac{\omega \vartheta \beta \nu + \omega \vartheta \hat{h}_t^2}{\beta \nu} + O^3. \tag{54}$$

This implies

$$\sum_{t=0}^{\infty} \beta^t \left[ \beta \nu \hat{h}_t^e + \omega \vartheta \left( \hat{h}_t + z^h \hat{h}_t \right) \right] = -\frac{\omega \vartheta}{2} \sum_{t=0}^{\infty} \beta^t \left( \frac{\beta \nu + \omega \vartheta}{\beta \nu} \hat{h}_t^2 - 2z^h \hat{h}_t \right) + O^3$$

$$= -\frac{\omega \vartheta}{2} \frac{\beta \nu + \omega \vartheta}{\beta \nu} \sum_{t=0}^{\infty} \beta^t \left( \hat{h}_t - \hat{h}_t^e \right)^2 + t.i.p. + O^3, \tag{54}$$

where in the second equality we have used the definition of the efficient level of housing, $\hat{h}_t^e = [\beta \nu / (\omega \vartheta + \beta \nu)] z^h$.

It is possible to show (see e.g. Woodford, 2003) that

$$\sum_{t=0}^{\infty} \beta^t \Delta_t = \varepsilon \frac{\theta}{2} \frac{1}{(1 - \theta) (1 - \beta \theta)} \sum_{t=0}^{\infty} \beta^t \hat{\pi}_t^2 + t.i.p. + O^3. \tag{55}$$

Using (54) and (55) in (52), we finally obtain

$$\sum_{t=0}^{\infty} \beta^t U_t = -\frac{1}{2} \sum_{t=0}^{\infty} \beta^t L_t + t.i.p. + O^3, \tag{56}$$

where

$$L_t = \frac{1 + \varphi}{1 - \nu} (\bar{y}_t - \bar{y}_t^*)^2 + \omega (1 - \omega) (\hat{c}_t - \bar{c}_t^e)^2 + \omega \vartheta \frac{\beta \nu + \omega \vartheta}{\beta \nu} \left( \hat{h}_t - \hat{h}_t^e \right)^2 + \frac{\varepsilon \theta}{(1 - \theta) (1 - \beta \theta)} \hat{\pi}_t^2.$$

QED.
7.4 Log-linear equations

All variables in log-deviations from the efficient steady state. The log-linear constraints of the central bank’s problem are the following.

1. Household’s consumption Euler equation,

\[ \hat{c}_t = E_t \hat{c}_{t+1} - E_t \left( \hat{R}_t^D - \pi_{t+1} \right). \]

2. Household’s demand for housing,

\[ (1 + \tau^h) (\hat{p}_t^h - \hat{c}_t) = (1 + \tau^h - \beta) \left( \hat{z}_t^h - \hat{h}_t \right) + \beta E_t (\hat{p}_{t+1}^h - \hat{c}_{t+1}). \]

3. Entrepreneur’s borrowing constraint,

\[ \hat{b}_t = z_t^m + E_t \hat{p}_{t+1}^h + \hat{h}_t^e - \left( \hat{R}_t^L - E_t \pi_{t+1} \right). \]

4. Entrepreneur’s consumption Euler equation,

\[ \hat{c}_t^e = \beta^e R_{ss}^L E_t \left( \hat{c}_{t+1}^e - \hat{R}_t^L + \pi_{t+1} \right) - \left( 1 - \beta^e R_{ss}^L \right) \hat{c}_t. \]

5. Entrepreneur’s demand for real estate,

\[ \hat{p}_t^h - \hat{c}_t^e = \beta^e E_t \left\{ \left( \frac{1 - \tau^e}{s_h^e} \nu \right) \left( \hat{y}_{t+1} + \hat{p}_{t+1}^l - \hat{h}_t^e \right) + \hat{p}_{t+1}^h - \left[ \frac{1 - \tau^e}{s_h^e} \nu \right] + 1 \right\} \hat{c}_{t+1}^e \]
\[ + m \left( \frac{1}{R_{ss}^L} - \beta^e \right) \left[ z_t^m + \hat{c}_t + E_t \hat{p}_{t+1}^h - \left( \hat{R}_t^L - E_t \pi_{t+1} \right) \right], \]

where \( s_h^e \equiv p_{ss}^h h_{ss}^e / y_{ss} \).

6. Entrepreneur consumption,

\[ \hat{c}_t^e = \frac{1 - \beta^e}{1 - \omega} \left[ (1 - \tau^e) \nu \left( \hat{y}_t + \hat{p}_l^e \right) + s_h^e \left( \hat{p}_t^h + \hat{h}_{t-1}^e \right) - s_h^e m \left( \hat{R}_{t-1}^L + \hat{b}_{t-1} - \pi_t \right) \right]. \]
7. Bank lending margin,

\[
\hat{R}_t^L = \hat{R}_t^D + \frac{\beta R^L_{ss} - 1}{\beta R^L_{ss}} \left[ \frac{\hat{R}_t^D + \hat{p}_t^h - m \beta E_t (\hat{\pi}_{t+1} + \hat{p}_{t+1}^h + z_t^m)}{1 - m \beta} - \frac{\eta m \beta E_t (\hat{\pi}_{t+1} + \hat{p}_{t+1}^h + z_t^m) - (\hat{R}_t^D + \hat{p}_t^h)}{\eta m \beta - 1} \right]
\]

8. New Keynesian Phillips curve,

\[
\hat{\pi}_t = \frac{(1 - \theta) (1 - \beta \theta)}{\theta} \hat{p}_t^I + \beta E_t \hat{\pi}_{t+1}.
\]

9. Real marginal costs,

\[
\hat{p}_t^I = \hat{c}_t - \hat{y}_t + \frac{1 + \varphi}{1 - \nu} \left( \hat{y}_t - a_t - \nu \hat{h}_{t-1} \right).
\]

10. Equilibrium in goods markets,

\[
\hat{y}_t = \omega \hat{c}_t + (1 - \omega) \hat{c}_t^e.
\]

11. Equilibrium in the real estate market,

\[
\hat{h}_t = \frac{\beta \nu}{\omega \theta} \hat{h}_t^e.
\]
