## **Abstract**

In this paper, we put forth the view that the potential for urbanisation economies increases with interaction opportunities. On the basis of that premise, three properties are key to an agglomeration index, which should: (i) increase with the concentration of population and conform to the Pigou-Dalton transfer principle; (ii) increase with the absolute size of constituent population interaction zones; and (iii) be consistent in aggregation. Confining our attention to pairwise interactions, and invoking the space-analytic foundations of local labour market area (LLMA) delineation, we develop an index of agglomeration based on the number of interaction opportunities per capita in a geographical area. This leads to Arriaga's mean city-population size, which is the mathematical expectation of the size of the LLMA in which a randomly chosen individual lives. The index has other important properties. It does not require an arbitrary population threshold to separate urban from non-urban areas. It adapts readily to situations where an LLMA lies partly outside the geographical area for which agglomeration is measured. Finally, it can be satisfactorily approximated when data are truncated or aggregated into size classes. We apply the index to the Spanish NUTS III regions, and evaluate its performance by examining its correlation with the location quotients of several knowledge-intensive business services (KIBS) known to be highly sensitive to urbanisation economies. The Arriaga index correlations are clearly stronger than those of either the classical degree of urbanisation or the Hirshman-Herfindahl concentration index.

## Resumen

La relevancia de las economías de aglomeración tipo urbanización sobre múltiples variables y/o dinámicas económicas se encuentra ampliamente documentada en la literatura. Sin embargo, es difícil ofrecer una medida sintética del nivel de aglomeración urbana que alcanza un territorio. En este trabajo se propone un índice de aglomeración que cumple tres propiedades fundamentales: i) aumentar en función de la concentración de la población y cumplir el principio de transferencia de Pigou-Dalton; ii) aumentar con el tamaño absoluto del territorio donde se producen interacciones de la población, y iii) ser consistente en la agregación. Se desarrolla un índice de aglomeración en función del número de oportunidades de interacción por habitante en un área geográfica, que considera las interacciones de pares y la delineación espacial de mercados de trabajo locales (LLMA, por sus siglas en inglés). La medida es la esperanza matemática del tamaño del LLMA donde vive un individuo aleatorio y se asemeja a la propuesta de Arriaga (1970, 1975). Adicionalmente, el índice posee varias características importantes. No requiere un umbral de población arbitraria para separar urbano de no urbano. Se puede adaptar a los casos en los que un LLMA radica en parte fuera de la zona geográfica para la que se mide la aglomeración. Finalmente, se puede aproximar de forma adecuada cuando hay datos truncados o con una elevada agregación. Para evaluar el funcionamiento del índice, se examina su correlación con los coeficientes de localización de las actividades de servicios a empresas intensivos en conocimiento, de las provincias españolas. Las correlaciones son claramente más elevadas que las obtenidas con el índice clásico de urbanización o el índice de concentración de Hirschman-Herfindahl.

## 1 Introduction

Typically, the relationship between development and urbanization is illustrated with a graph plotting the degree of urbanization (fraction of population living in an urban area) against GDP per capita or its rate of growth. This is true of international comparisons (Henderson, 2003, p. 281; Annez and Buckley, 2009, Annex 2), as well as regions (Crédit Suisse, 2012, p. 16; Zhu et al., 2012, Fig. 2). Urban concentration has also been the subject of much attention in relation to economic development. Indeed, about the urbanization process that occurs with development, Henderson (2003b) writes: “There are two key aspects to the process. One is urbanization itself and the other is urban concentration [...]”. Brülhart and Sbergami (2009) also measure agglomeration alternatively through urbanization shares and through indices of spatial concentration. In this paper, we develop a measure which combines both aspects.

Specifically, the issue we address is how to measure urbanization, using readily available data, in a way that reflects the potential for agglomeration economies of the urbanization type. Our approach is founded on the view that agglomeration provides opportunities for interactions between economic agents, a key mechanism by which urbanization economies are generated. Our measure will therefore be closely related to the view of an “urban area” as an integrated market. And as it turns out, we “rediscover” an index originally proposed by demographer Eduardo Arriaga (1970, 1975) as a measure of urbanization. That index possesses three properties that are fundamental for a measure of agglomeration: (i) it increases with the concentration of population and conforms to the Pigou-Dalton transfer principle; (ii) it increases with the absolute size of constituent population interaction zones; and (iii) it is consistent in aggregation. The index has other important properties: it does not require an arbitrary population threshold to separate urban from non-urban areas; it is easily adapted to situations where a population zone lies partly outside the geographical area for which agglomeration is measured (boundary problem); and it can be satisfactorily approximated when data is truncated or aggregated into size-classes.

The rest of this paper is organized as follows. The next section presents a view of urbanization economies resulting from opportunities for interaction. Ensurue the three fundamental properties that an agglomeration index should possess. Concentration measures, in particular, fail to meet these conditions, but Arriaga’s index does. The next section develops Arriaga’s index from our theoretical view of agglomeration and discusses its properties. Then the index is computed for the Spanish NUTS III regions, and its performance is compared to that of the degree of urbanization and the Hirshman-Herfindahl concentration index. A concluding section completes the paper.

## 2 Measuring urban agglomeration as opportunities for interaction

A tailor, a physician and a sports coach all take measurements of the human body. But for different purposes, they use different measures. How should we measure agglomeration for the purpose of examining the potential for agglomeration economies of the urbanization type (urbanization economies, for short)? To answer that question, we need to have a theory, a model, or at least a general view of how urbanization economies arise.

The concept of *Agglomeration economies*, first proposed by Weber (1909), is central in regional and urban economics. Ohlin (1933), Hoover (1937) and Isard (1956) clarify the idea and distinguish different types of *agglomeration economies*: (i) *large-scale* economies, (ii) *localization* economies and (iii) *urbanization* economies. Here we are concerned with urbanization economies, and more specifically with urbanization economies insofar as they are the result of interaction between economic agents. The concentration of population in an urban area multiplies opportunities for interaction; the greater the number of possible interactions, the greater the potential for urbanization economies, as proximity encourages formal and informal exchanges of ideas which nourish innovation and contribute to the diffusion of knowledge (knowledge spillovers). Consequently, the measure we are looking for is a measure of opportunities for interaction. This aspect of urbanization economies has been examined by Glaeser *et al.* (1992) in relation to city growth. The authors compare the evolution of employment in individual industries across cities, to confront the predictions of competing views of how knowledge spillovers stimulate growth (specialization vs. diversity; competition vs. monopoly and the internalization of externalities). In this paper, however, we deal with a different issue, namely, measuring opportunities for interaction in a geographical area (region, group of regions, country) that may comprise several cities, or a single city, or even none at all (a region of villages, for example).

Now, in the abstract, restricting our attention to interaction between pairs of individuals, the number of possible pairs in a group increases as the square of the number of individuals<sup>1</sup>. Not all links, however, are equally probable: distance (physical or social) may impede communication, and congestion may interfere with exchanges. But, practically speaking, it is impossible to weigh all pairs according to distance and congestion factors. Yet these can be taken into account indirectly, using labor mobility as an indicator of whether interactions are likely or not.

Local labor market areas (LLMAs) are delineated on the basis of labor mobility, so they are well-suited as basic territorial units for examining interaction-based urbanization economies. Labor mobility is also a key criterion used by statistical agencies to circumscribe metropolitan or urban areas. Consequently, an LLMA cannot in principle comprise only part of a metropolitan or urban area. LLMAs may (and do) however transcend municipal boundaries and include several population nuclei, as do metropolitan areas. But, contrary to metropolitan and urban areas, the set of LLMAs covers the whole territory, not just the main urban areas (it is a partition of the territory). It follows that any area that would not be comprised in any metropolitan or urban area is nonetheless included in some LLMA; so LLMAs containing metropolitan areas may also contain some additional areas. And, of course, not all LLMAs are

---

1. The number of distinct pairs in a group of  $n$  individuals is equal to  $n(n-1)/2$ . If  $n$  is sufficiently large, this can be approximated by  $n^2/2$ . More generally, combinatorics shows that the number of interactions involving two persons or more increases more than proportionately with the size of the group.

metropolitan areas or even urban areas. The delineation of LLMA has been implemented in several countries<sup>2</sup>. The partitioning of geographic space into LLMA is an exercise in the spatial analysis of commuting patterns, in order to “define geographical units where the majority of the interaction between workers seeking jobs and employers recruiting labour occurs (i.e. to define boundaries across which relatively few people travel between home and work)” (Casado-Díaz, 2000). LLMA may transcend administrative boundaries and include several population nuclei.

Now, population is often used as an indicator of potential urbanization economies for a metropolitan area. In such case, when the focus is on opportunities for interaction, the implicit simplifying assumption is made that the interactions which matter are the ones taking place within the limits of the metropolitan area. The same simplifying assumption can be made regarding LLMA to estimate the number of interaction opportunities in each LLMA. And since LLMA define a partition of geographic space, including zones that would be classified as non-urban, it becomes possible to estimate the number of interaction opportunities for a region by aggregating the number of interaction opportunities in the LLMA that constitute the region, following the procedure detailed below. Finally, to relate the number of interaction opportunities to productivity (output per unit of input), it must be divided by population. By computing interaction opportunities at the LLMA level before aggregating, we use the labor mobility criterion which defines LLMA to determine which interactions are likely or not. This is how we implicitly take into account distance decay<sup>3</sup>.

What does this interaction-based view of agglomeration tell us about how to measure the possibility of urbanization economies? First, since the number of opportunities for interaction increases more than proportionately with population, an agglomeration index should increase with concentration. More specifically, an agglomeration index should conform to (an inverted form of) the Pigou-Dalton transfer principle<sup>4</sup>: the number of opportunities created by moving one person to a larger LLMA (increasing concentration) is greater than the number of opportunities destroyed by his/her leaving the smaller LLMA. Second, a measure of concentration only is not a proper agglomeration index, because concentration is a property of the distribution of population between LLMA, and it is insensitive to their sizes: there are more interaction opportunities *per capita* in a region consisting of two LLMA with populations of 150,000 and 50,000 than in a region consisting of two LLMA with populations of 15,000 and 5,000; or, to take an absurd example, a desert with a single inhabitant is 100% concentrated, but offers no opportunities for interaction. Third, an agglomeration index should be consistent in aggregation: the same rule that is applied to aggregate individual LLMA agglomeration indexes into a regional index should also be valid to aggregate regional indexes into an agglomeration index of a group of regions.

There are other desirable properties, which will be discussed later. Since there are interaction opportunities even in the smallest of villages, an agglomeration index should be defined without reference to a population threshold below which an area is excluded from calculations. On the other hand, data is sometimes truncated, or aggregated into size-classes,

---

2. Among which (in alphabetical order): Canada (Munro *et al.*, 2011); France (DATAR-DARES-INSEE, 2011); Italy (ISTAT, 1997, 2005, 2006; Sforzi, 2012); New Zealand (Statistics New Zealand, 2009; Goodyear, 2008; Papps and Newell, 2002); Portugal (Alfonso and Venâncio, 2013); Spain (Rubiera and Viñuela, 2012; Boix and Galleto, 2006); United Kingdom (Bond and Coombes, 2007; ONS, 2007); USA (Tolbert and Sizer, 1996; USDA ERS, 2012).

3. However, our index does not take into account negative congestion externalities. Referring to Capello and Camagni (2000), it could be said that our index is one component of a “city effect indicator” of positive externalities, while leaving aside congestion externalities which could be accounted for in an “urban overload indicator”.

4. Dalton (1920, p. 351); Pigou (1912, p. 24). Also Cowell (2009).

so it would be advantageous to be able to adapt an agglomeration index to such circumstances. More generally, an index with modest data requirements is more susceptible of application. Another attractive property is the possibility of computing an agglomeration index for a region that includes only part of some LLMA's (more about the boundary problem below).

Let us now examine measures of urbanization found in the literature to see whether they have the fundamental properties enunciated above, namely: (1) to increase with the concentration of population and conform to the transfer principle; (2) to increase with the absolute size of constituent LLMA's; and (3) to be consistent in aggregation. The *degree of urbanization* (percentage of population living in an urban area) fails as a measure of agglomeration with respect to all three criteria, in addition to raising the difficulty of drawing a line between urban and non-urban.

Much of the literature on urbanization and development, however, focuses on the relationship between urban concentration and economic development or productivity. Yet, by definition, measures of concentration do not satisfy our second criterion. As a matter of fact, according to Cowell (2009), a measure of concentration (which Cowell applies to measure income inequality) should satisfy the "income scale independence principle", which, transposed to the measurement of agglomeration, is the exact opposite of our second criterion of an interaction-based measure of agglomeration. It will nonetheless be useful to briefly review urban concentration measures. Wheaton and Shishido (1981) and Henderson (1988) use the Hirshman-Herfindahl index, to which we shall return later. In the present context, it is defined as the sum of squared population shares of LLMA's<sup>5</sup>. Henderson (2003a, 2003b) uses *urban primacy*, the share of urban population that lives in the largest city. It does not satisfy the transfer principle, but Henderson argues that it is conveniently available for many years and many countries, and that it is closely correlated with Hirshman-Herfindahl indices. Rosen and Resnick (1980)<sup>6</sup> measure urban concentration using the econometrically estimated exponent of the Pareto distribution for the city-size distributions of 44 countries. They find that it is quite sensitive to the definition of the city and the choice of city sample size (number of cities or city-population threshold). Brühlhart and Sbergami, (2009) apply Theil entropy indexes developed in Brühlhart and Traeger (2005). But, as mentioned earlier, these are all concentration measures which fail to satisfy our second criterion.

Uchida and Nelson (2010) look for a remedy to inconsistencies in published UN data on the degree of urbanization which are due to divergences between reporting countries in the way they delineate urban areas and in the population thresholds applied to define what is urban and what is not. They propose an "agglomeration index" which focuses on the key indicators of the sources of agglomeration economies: population density, the size of the population in a "large" urban centre, and travel time to that urban centre. Combining data from several sources (including GIS data on transport networks), and applying interpolation techniques, they map all three factors on the surface of the earth in one-kilometer pixels. For each of the three factors, a threshold is defined, and the estimated population in pixel areas that meet all three criteria is classified as "urban". This yields an estimate of the degree of urbanization. The Uchida-Nelson agglomeration index approach is promising, but it remains tied to the urban/non-urban dichotomy and as such, it fails all three of the criteria mentioned above.

---

5. Although frequently applied as a index of urban concentration within a country, it was originally proposed as a measure of market concentration, or market power.

6. Mentioned by both Henderson (2003b) and Wheaton and Shishido (1981).

Reflecting on the weaknesses of the percentage of population living in “urban areas” as a measure of urbanization, demographer Eduardo Arriaga (1970, 1975) proposed an index which “takes into account the statistical concept of the expected value of the size of the locality where a person, randomly chosen, resides” (p. 208). In the following section, we develop an index based on interaction opportunities, which turns out to be Arriaga’s index applied to LLMAAs. This index, as we shall see, satisfies all three basic conditions listed above.

### 3 Arriaga's index applied to LLMA's

#### 3.1 Arriaga's index as a measure of interaction opportunities

We derive Arriaga's agglomeration index from our view of urbanization economies as the result of interaction between economic agents. In so doing, we make two simplifying assumptions. First, we limit our attention to *pairwise* interactions, so that the number of interaction opportunities among  $n$  persons is  $n(n-1)/2$ , which we approximate as  $n^2/2$ . Second, invoking the space-analytic foundations of LLMA delineation, we take into account interaction opportunities within LLMA's, while ignoring interactions that may take place across LLMA's.

Formally, let  $n_i$  be the population size of the  $i^{\text{th}}$  LLMA in the geographical area under consideration. Then the total amount of interaction opportunities is approximated as  $\frac{1}{2} \sum_i n_i^2$ .

We relate productivity (output per unit of input) to the number of interaction opportunities of the average individual, which leads to the following measure of agglomeration:

$$\text{Measure of agglomeration} = \frac{\sum_i n_i^2}{2 \sum_i n_i} \quad [1]$$

Expression [1] is precisely one half of Arriaga's mean city-population size. Now let

$$f_i = \frac{n_i}{\sum_j n_j} \quad [2]$$

be the fraction of population in the  $i^{\text{th}}$  LLMA. Dropping the division by 2, we have an index of agglomeration defined as

$$I = \frac{\sum_i n_i^2}{\sum_i n_i} = \sum_i \left( \frac{n_i}{\sum_j n_j} \right) n_i = \sum_i f_i n_i \quad [3]$$

This is Arriaga's (1970) index. His interpretation of the index stands out from formula [3]<sup>7</sup>: since  $f_i$  is the probability that a randomly chosen individual reside in the  $i^{\text{th}}$  LLMA, then  $I$  is the mathematical expectation of the size of the LLMA in which a randomly chosen individual lives<sup>8</sup>. In other words, the average individual lives in an LLMA of size  $I$ .

<sup>7</sup> Arriaga investigates the implications of using a truncated index which ignores the bottom end of the size distribution of agglomerations, and concludes that a truncated index is a good approximation, under mildly restrictive hypotheses. But in our case, there is no truncation, because the LLMA's cover the whole territory. Lemelin *et al.* (2012, Appendix I) present a version of the index that is based on information aggregated by size classes and therefore deals with truncation.

<sup>8</sup> We assume that each individual has an equal probability of being chosen, in which case relative frequencies are correctly interpreted as probabilities.

Let us pursue the development, substituting from [2], we find:

$$I = \sum_i f_i n_i = \left( \sum_j n_j \right) \sum_i f_i \left( \frac{n_i}{\sum_j n_j} \right) = \left( \sum_j n_j \right) \sum_i f_i^2 \quad [4]$$

where:

$$H = \sum_i f_i^2 \quad [5]$$

is the Hirschman-Herfindahl (HH) concentration index. So:

$$I = \left( \sum_j n_j \right) H \quad [6]$$

Our index is the HH concentration index, multiplied by the total population in the geographical area under consideration. This illustrates how it accounts for both concentration and size, which we consider as two aspects of the potential for economies of agglomeration of the urbanization type.

The reader may be surprised that the index takes the same value  $I = n$  for a territory with a single LLMA of size  $n$  as it does for a territory with  $K$  LLMAs, all of size  $n$ . This is true, and it is as it should be. It can be seen from equation [6] that in the first case,  $I = n \times 1$ ; in the second, using the numbers equivalent property<sup>9</sup> of  $H$ ,  $I = (K \times n) (1/K) = n$ , as greater size makes up for less concentration. In both cases, the average individual lives in an LLMA of size  $n$  (following Arriaga's interpretation). Insofar as  $I$  measures the average individual's interaction opportunities, the potential increase in productivity associated with agglomeration economies is equal in both cases.

Finally, Arriaga's index has an interesting geometric interpretation: in a graph of the stepwise cumulative distribution of population according to LLMA sizes, it is the area above the curve. We illustrate this using fictitious data as an example. Table 1 gives the population of each of 5 LLMAs in some geographic area under investigation.

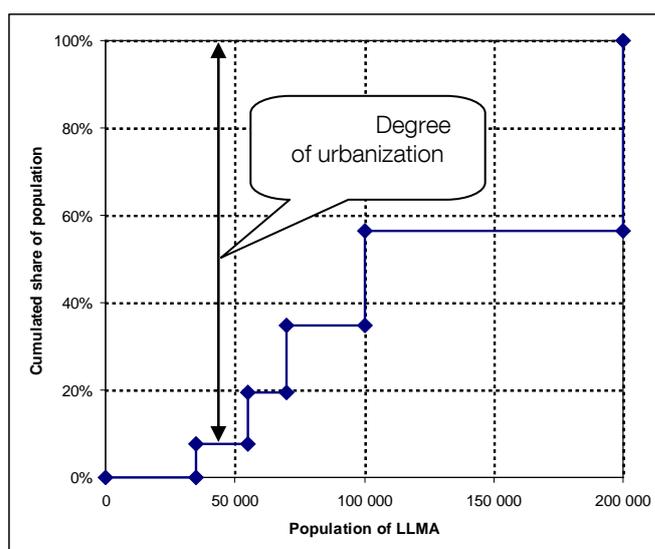

**Table 1. Fictitious data**

	(1) Population	(2) Population share (%)	(3) Cumulated population	(4) Cumulative distribution (%)
<b>LLMA 1</b>	35 000	7.6	35 000	7.6
<b>LLMA 2</b>	55 000	12	90 000	19.6
<b>LLMA 3</b>	70 000	15.2	160 000	34.8
<b>LLMA 4</b>	100 000	21.7	260 000	56.5
<b>LLMA 5</b>	200 000	43.5	460 000	100.0
<b>Total</b>	<b>460 000</b>			

9. Adelman (1969) has shown the "numbers-equivalent" property of the Hirschman-Herfindahl index ( $H$ ): its inverse ( $1/H$ ) can be interpreted as the number of equal-sized LLMAs which would exhibit a concentration level equal to  $H$ .

As mentioned before, a common measure of the degree of urbanization is the proportion of population living in urban areas above a certain size. For instance, given the data in Table 1, the degree of urbanization could be measured as the proportion of population living in LLMA's with a population of at least 50 000. In our example this would be 92.4% (425 000 / 460 000). Referring to the distribution of population (Table 1, column 2), this way of measuring urbanization amounts to lumping together all categories but the first. The conventional measure of urbanization is therefore based on a highly simplified representation of the more detailed distribution of population, represented in Figure 1. It is completely insensitive to the distribution of population among the LLMA's with more than 50 000 inhabitants.

**Figure 1 – Cumulative distribution of population according to LLMA sizes**

Let  $K$  be the number of LLMA's in the geographical area under consideration (here 5). Then the area above the curve is equal to:

$$I = \sum_{i=1}^K (1 - F_{i-1})(n_i - n_{i-1}) \quad [7]$$

where LLMA's are assumed to be ordered from smallest to largest, and  $F_i = \sum_{j=1}^i f_j$  is the cumulative distribution. In our example, this is equal to 0.0242. It is shown in the appendix that [7] is equivalent to [3].

Before moving on to examining the properties of the index, it should be pointed out that Arriaga's original presentation dealt not with LLMA's, but with traditional city-population data. Arriaga examined the sensitivity of his index to the choice of an urban threshold, a cut-off point in the distribution below which localities are classified as rural and excluded from the computation of the index; he found that it was pretty robust.

### 3.2 Properties of the index

To start with, the domain of the Arriaga index is well defined. It is non-negative, and its lower bound is zero. This extreme case would be approximated if all of the population lived in rural

areas, in very small autarkic villages (of, say, 100 inhabitants); the cumulative distribution curve would then be close to an upside-down «L», with the horizontal line at the 100% level, and the vertical line at the 100 population level. The upper bound of the index is equal to the population of the largest LLMA in the geographical area under consideration, and would occur if all population were concentrated in that largest LLMA. The curve would then be a mirror-image of an «L», with the vertical bar to the right.

### 3.2.1 AXIOMATIC PROPERTIES

We now verify whether the Arriaga index possesses the fundamental properties of an agglomeration index. Considering equation [6], the value of the index clearly increases with concentration as measured by the HH index<sup>10</sup>. Moreover, it is demonstrated in the appendix that it conforms to the transfer principle. Second, once again turning to equation [6], the index clearly increases with the average size of LLMA.

Let us examine whether the Arriaga index is consistent in aggregation. First, notice that, for a geographical area containing a single LLMA of population  $n$ , formula [3] shows that the value of the index is simply  $n^2/n=n$ . The same formula shows that for  $K$  LLMA, the value of the index is a weighted average of individual LLMA indices  $n_i$ , where the weights  $f_i$  are the population shares of LLMA. Now consider a geographical area of interest partitioned into two regions, defined by a pair of complementary sets  $A$  and  $\bar{A}$ : the  $i^{\text{th}}$  LLMA belongs to one region if  $i \in A$ , and to the other if  $i \notin A$ . Now let

$$F_A = \left( \frac{\sum_{i \in A} n_i}{\sum_i n_i} \right) \text{ and } F_{\bar{A}} = \left( \frac{\sum_{i \notin A} n_i}{\sum_i n_i} \right) = 1 - F_A \quad [8]$$

where  $F_A$  is the fraction of population that lives in an LLMA belonging to the set  $A$  of LLMA that constitute one region, while  $F_{\bar{A}}$  is the fraction of population that lives in the other region. Also let

$$f_{i|A} = \frac{n_i}{\sum_{j \in A} n_j} = \frac{n_i}{\sum_j n_j} \frac{\sum_j n_j}{\sum_{j \in A} n_j} = \frac{f_i}{F_A} \text{ and likewise, } f_{i|\bar{A}} = \frac{f_i}{F_{\bar{A}}} \quad [9]$$

According to formula [3], we have

$$I_A = \sum_{i \in A} f_{i|A} n_i \text{ and } I_{\bar{A}} = \sum_{i \notin A} f_{i|\bar{A}} n_i \quad [10]$$

Recalling that  $n_i$  is the agglomeration index of the  $i^{\text{th}}$  LLMA, formula [3] applied to the two regions translates as

---

<sup>10</sup>. It does not, however, increase monotonically with the Pareto parameter interpreted as a measure of concentration. The reason for this is exposed in the appendix.

$$I = F_A I_A + (1 - F_A) I_{\bar{A}} \quad [11]$$

Substitute from [9] and [10], and use  $F_{\bar{A}} = 1 - F_A$  to find

$$I = F_A \sum_{i \in A} \left( \frac{f_i}{F_A} \right) n_i + F_{\bar{A}} \sum_{i \notin A} \left( \frac{f_i}{F_{\bar{A}}} \right) n_i = \sum_i f_i n_i \quad [12]$$

So indeed, the same rule that is applied to aggregate individual LLMA agglomeration indexes into a regional index is also valid to aggregate regional indexes into an agglomeration index of a group of regions.

### 3.2.2 BOUNDARY PROBLEM AND OTHER APPLICABILITY CONSIDERATIONS

So far, the Arriaga index has been developed under the assumption that every LLMA is entirely contained in the geographical area for which the index is to be computed. But this cannot be guaranteed, since LLMA are delineated without regard for administrative boundaries<sup>11</sup>. Let  $f_{ir}$  be the fraction of the population in region  $r$  residing in the  $i^{\text{th}}$  LLMA. Then, bearing in mind Arriaga's (1970) interpretation, the average size of the LLMA where a randomly chosen individual lives is given by a formula slightly different from [3]:

$$I_r = \sum_i f_{ir} n_i \quad [13]$$

where  $f_{ir}$  replaces  $f_i$ . Equation [13] is the way to compute our index for regions when LLMA extend across regional boundaries. Now, however, the tight relationship with the HH concentration index breaks down.

To sum up, the Arriaga index applied to LLMA satisfies the three fundamental properties of an agglomeration index. It is less difficult to compute than the Uchida and Nelson (2010) agglomeration index, while implicitly taking into account their three criteria – population density, the size of a “large” urban centre, and travel time – through the spatial-analytic underpinnings of LLMA delineation, and without the requirement of defining an arbitrary urban threshold. On the other hand, if a delineation of LLMA is not available, the Arriaga index is applicable to traditional city-population data, although it is preferable that “cities” be defined as functional areas as are metropolitan areas (in general, every metropolitan area is an LLMA). Finally, we have shown elsewhere<sup>12</sup> that it would also be possible to compute the index, and obtain similar results, when the underlying population data is available only in LLMA size-categories, rather than for individual LLMA.

<sup>11</sup>. Such is the case in Spain, for example, where several LLMA include spatial units that are located in more than one province.

<sup>12</sup>. Lemelin *et al.* (2012, Appendix 1).

## 4 Empirical application

In this section, we apply this index to the Spanish provinces (NUTS III regions), using LLMAAs as basic units for the construction of the index. Spain is a very good example because data availability forces much of the empirical research to be conducted at the NUTS II or NUTS III levels, even though a different geography may be preferable. Most of the economic information provided by the Spanish National Statistical Institute (INE) (GDP, stock of capital, wages or employment data...) is available only for the whole country or at the NUTS III level. There is little data available at a finer level of geographical detail, such as municipalities. To find geographically disaggregated economic information, one has to look up some very specific databases or use the data provided by taxes or unemployment registers. This scarceness of finer information also prevails in many other countries. Fortunately, detailed population data is often available. And from detailed population data, it is possible to construct the Arriaga index and put the degree of agglomeration in relation with other key economic concepts such as regional productivity or growth.

### 4.1 The Spanish provinces

Administratively, Spain is divided into 8 105 municipalities that are aggregated into 52 provinces (NUTS III level) and 17 Autonomous Communities or NUTS II regions. The number of municipalities within each province ranges from 34 (Las Palmas) to 371 (Burgos). Furthermore, there are Autonomous Communities with several provinces (for example, Andalusia with eight), and others with only one, like Asturias. For comparison with other European Union member-states, the seventeen Autonomous Communities can be aggregated into seven administrative regions or NUTS I regions, which have no real internal political or administrative meaning.

It is important to point out that municipalities are not the basic territorial units from which we construct our index. In Spain, a municipality is an administrative division of the territory which has not necessarily been defined with economic significance in mind. Indeed, in many cases, there is a high level of commuting between neighboring municipalities. And so municipalities have been aggregated into LLMAAs which may transcend municipal boundaries, and eventually make up a metropolitan area, which might include several population nuclei surrounding a core one. To delineate LLMAAs in Spain, Boix and Galleto (2006) have applied the regionalization method developed for Italy by Sforzi (ISTAT, 1997, 2005, 2006; Sforzi, 2012). The Spanish LLMAAs have been delineated through a multi-stage process. Applying an algorithm that consists of four main stages and a fifth stage of fine-tuning, Boix and Galleto aggregate the 8 106 Spanish municipalities into 806 LLMAAs. The algorithm starts with the municipal administrative unit and it generates the LLMAAs using data on resident employed population, total employed population and home-to-work commuting, from the 2001 Spanish Population and Housing Census (INE)<sup>13,14</sup>.

The LLMAA data is used to compute the Arriaga index of urban agglomeration for each province. Since there are LLMAAs which straddle provincial boundaries, the actual formula used in the calculations is equation [13], developed above to deal with the boundary

---

<sup>13</sup>. This is the most recent data as the 2011 Spanish Population and Housing Census (INE) is not yet available.

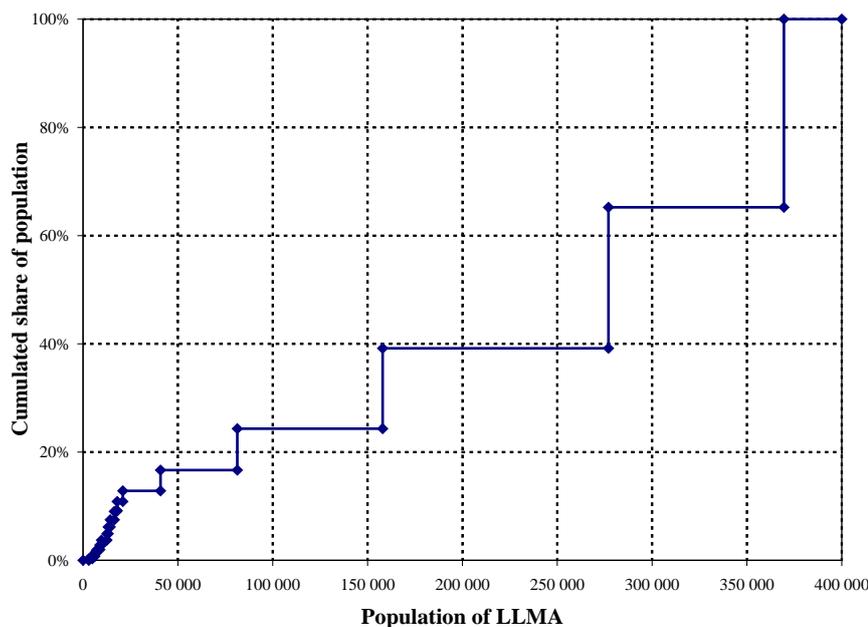

<sup>14</sup>. More details and applications of LLMAAs are found in Fernandez and Rubiera (2012). Rubiera and Viñuela (2012) perform an economic evaluation of this spatial unit.

problem<sup>15</sup>. Finally, for ease of presentation, all index values were divided by the population of the Madrid LLMA, the largest in the country, so that their range of variation is from 0 to 1.

#### 4.2 Comparison of the indexes

Figure 2 represents the cumulative distribution of population according to LLMA size for the province of Asturias, 2001 (similar to Figure 1). The area above the curve is equal to the Arriaga index, the value of which is 233 637, or 4.4% of the population of the Madrid LLMA.

**Figure 2 – Cumulative distribution of population according to LLMA size, Asturias (2001)**

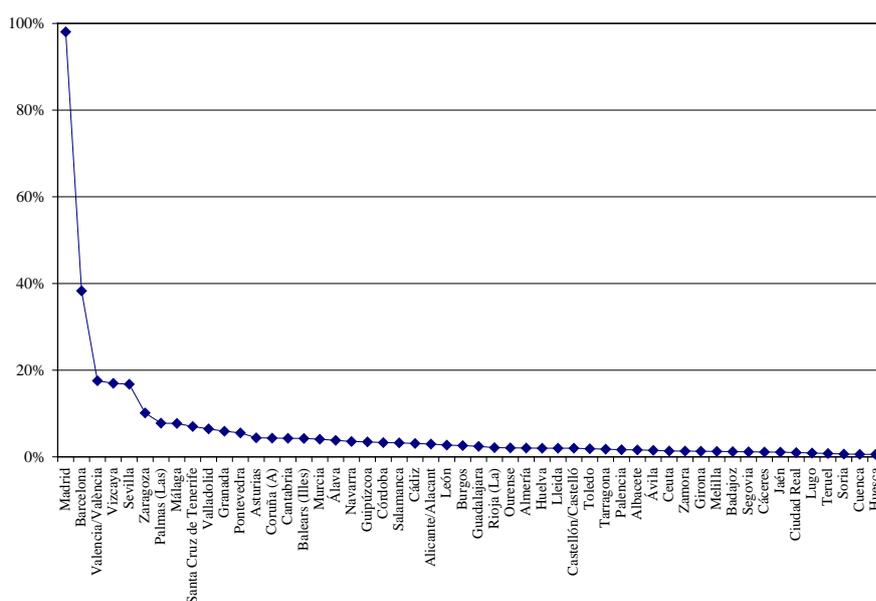

Source: Own based on INE (2001) data.

All the Spanish provinces are plotted in Figure 3, ranked by the value of the index. Madrid is followed by Barcelona and, at a much greater distance by Vizcaya, Valencia and Seville, which contain cities among the biggest in the country. At the opposite end are located the provinces with the lowest population densities of the country (Huesca, Cuenca, Soria and Teruel).

<sup>15</sup> In Appendix II of Lemelin *et al.* (2012), this is compared with an index for which each LLMA has been attributed in its entirety to the province where its centroid is located, which is tantamount to redrawing provincial boundaries. Interestingly, at least in the Spanish case, the two versions of the index are tightly correlated across the 52 provinces.

**Figure 3 – Arriaga index for Spanish provinces, 2001**  
 (% of Madrid LLMA population)

Source: Own based on INE (2001) data.

Figure 4 plots the HH index of urban concentration and Figure 5 the classical degree of urbanization (the percentage of population living in cities of more than 50 000 inhabitants). Of course, the HH index and the classical degree of urbanization do not measure the same thing as our index (see section 2 above). The purpose of Figures 4 and 5 is to show how ranking provinces according to the HH index or the classical degree of urbanization leads to obvious aberrations if one wants to compare provinces with respect to their potential for interaction-based urbanization economies. Both figures display several aberrations. Ceuta and Melilla, two autonomous cities located in North Africa, with a joint population of less than 140 000 inhabitants in 2001, stand at the top of the hierarchy, with a 100% degree of urbanization and a HH index of 1. The province of Teruel has no LLMA of 50 000 inhabitants or more, so its degree of urbanization is zero, and the tail-end of the curve in Figure 5 drops abruptly. In spite of this, and although it is the fourth least populated province of Spain with the second lowest density, Teruel ranks significantly better, 39<sup>th</sup>, with respect to the HH index; the Arriaga index puts it in 49<sup>th</sup> position. There are other cases of misrepresentation with the HH index: for example, Alicante is in 50<sup>th</sup> position with respect to that index, but it occupies the 5<sup>th</sup> rank in Spain for population, and the 7<sup>th</sup> in terms of density; the Arriaga index, which takes into account both concentration and scale, ranks Alicante 24<sup>th</sup>. Barcelona, the province with the country's second largest city, is surprisingly ranked 15<sup>th</sup> according to the HH index. Aberrations also appear with the classical index: Sevilla, for instance, is the 4<sup>th</sup> largest province in terms of its population (1.7 million), 70% of which live in the Sevilla metropolitan area, the 4<sup>th</sup> largest city in Spain; yet it falls to the 18<sup>th</sup> place according to its degree of urbanization, and to 10<sup>th</sup> place according to the HH index, behind Álava with a mere 300 thousand in population and a much lower density. We quote two final examples of violent changes in ranking between the three indexes. Málaga, the 6<sup>th</sup> largest city in Spain, occupies the 18<sup>th</sup> place according to the classical index, but the 8<sup>th</sup> with Arriaga's (9<sup>th</sup> with the HH index); Guadalajara, among the least populated provinces, with one of the lowest densities in the country, ranks 7<sup>th</sup> with the HH index and 13<sup>th</sup> with the classical index, while it is 27<sup>th</sup> with Arriaga's. We conclude that the Arriaga index displays a more suitable classification of the

### 4.3 Index performance evaluation

To illustrate how our index is able to better capture economic patterns, we correlate it with the *location quotients* of some of the activities known to be highly sensitive to agglomeration economies of the urbanization type: high order producer services, also called knowledge intensive business services (henceforth KIBS). There are numerous empirical studies that use location quotients (alongside other measures) to confirm the tendency of these industries to concentrate in relation to agglomeration economies of the urbanization type<sup>17</sup>. Hence, we expect a good index of urban agglomeration to be highly correlated with the location quotients of these services, and among competing indexes, we would prefer the one with the highest correlation.

The location quotient (LQ) that we use is the simplest one, defined as follows:

$$LQ_{jp} = \frac{(e_{jp}/e_p)}{(E_j/E)} \quad [14]$$

where  $LQ_{jp}$  is the location quotient of sector  $j$  in province  $p$ ;  $e_{jp}$  is employment in sector  $j$  in province  $p$ ;  $e_p = \sum_j e_{jp}$  is total employment in province  $p$ ;  $E_j = \sum_{i=1}^n e_{jp}$  is the total employment in sector  $j$  in Spain ( $n$  is the number of spatial units: 52 provinces). Finally,  $E = \sum_j E_j$  is the total employment in Spain.

Table 2 shows the correlations between each index (the degree of urbanization, the HH concentration index and the Arriaga index), and the location quotients of eight high order producer-service industries. In all cases, the Arriaga index is more closely correlated than the others with the location quotients. The second part of Table 2 shows the same correlations, but without the two outlier observations Ceuta and Melilla (see above). Interestingly, the Arriaga index barely changes, while the two others improve substantially (but not to the point of becoming better than the Arriaga index); this may indicate that perhaps the Arriaga index deals more effectively with outliers.

---

<sup>17</sup> The reasons for the concentration of such services in large metropolitan areas are strongly connected with the presence of different types of effects directly derived from the existence of agglomeration economies. The diversity and rapidly changing nature of talents and know-how mean that only the largest cities will provide the necessary specialized labor pool. Such industries are, in other words, dependent on a constant stream of face-to-face meetings with a wide (and changing) range of individuals that only can occur in cities, but better in large cities. See Daniels (1985), Illeris (1996), Shearmur and Doloreux (2008), Polèse *et al.* (2007) or Wernerheim and Sharpe (2003), among many others.

Figure 6 illustrates the relationship between each of the three indexes and the location quotients of four of the KIBS industries. To make the graphs more legible, our proposed index is plotted against a logarithmic scale, which transforms the linear trend line into a curve.

For all these activities, the proposed index captures much better the effect of the main metropolitan areas of the country: Madrid, represented by the top right-hand point in the trend lines, and Barcelona, the first point to the left of Madrid. For the rest of the provinces, this index clearly displays a better fit between the location quotients of KIBS industries and the measure of urban agglomeration. As can be seen, the relation with both the degree of urbanization and the HH index, in many cases, shows apparent heteroskedasticity. The largest deviations from trend appear for the higher values of the index, that is, for the provinces where the biggest cities are. In addition, both the degree of urbanization and the HH index are equal to 1 for Ceuta and Melilla, two autonomous cities, located in North Africa, with a joint population of less than 140 000 inhabitants in 2001. In general, the degree of urbanization and the HH index account for concentration, but not for size. As a consequence, they take on high values for provinces with a population that is substantial, but not so large, concentrated around a medium-sized city. In such cases, these two indicators clearly overstate the interaction opportunities and the potential for urbanization economies. The Arriaga index, which takes account of both size and concentration, does not suffer from the same distortion.

## 5 Summary and conclusions

In this paper, we put forth the view that the potential for urbanization economies increases with interaction opportunities. From that premise follow three fundamental properties that an agglomeration index should possess: (i) to increase with the concentration of population and conform to the transfer principle; (ii) to increase with the absolute size of constituent LLMA; and (iii) to be consistent in aggregation. Concentration measures, in particular, fail to meet condition (ii).

We then develop an index of agglomeration based on the number of interaction opportunities per capita in a geographical area of interest. This is made possible thanks to two simplifying assumptions: (i) we limit our attention to *pairwise* interactions, and (ii) invoking the space-analytic foundations of LLMA delineation, we take into account interaction opportunities within LLMA, while ignoring interactions that may take place across LLMA. This leads to Arriaga's mean city-population size, which is the mathematical expectation of the size of the LLMA in which a randomly chosen individual lives.

We apply the Arriaga index to the Spanish provinces, and compare it to the degree of urbanization and the Hirshman-Herfindahl concentration index. We find that the three indexes rank the provinces quite differently. An examination of the more extreme cases of rank change shows that ranking according to the Arriaga index better reflects the geographical distribution of population, both with respect to size and concentration, and allows to correctly capture the potential for agglomeration economies from urbanization. Next, we correlate all three indexes with the location quotients of four knowledge intensive business services (KIBS) known to be highly sensitive to agglomeration economies of the urbanization type. We find that the Arriaga index clearly displays a better fit between the location quotients of KIBS industries and the measure of urban agglomeration, as is confirmed by the much higher correlation coefficients.

The index has other advantages. It does not require to define an arbitrary population threshold which excludes areas classified as non-urban from calculations. It is easily extended to accommodate situations where an LLMA lies partly outside the geographical area for which agglomeration is measured. Finally, its already modest data requirements can be weakened if necessary to compute a satisfactory approximation of the index using data that is truncated or aggregated into size-classes. All these properties, together with the fact that the practice of delineating LLMA is spreading among statistical agencies, make the index easily reproducible for different areas or countries and so, it will become increasingly convenient to use it.

Arriaga's index, both in its original version and applied to LLMA, is well rooted in a theoretical view of agglomeration economies, its data requirements are modest, and we have shown that, at least in the case of Spain, it performs better than other commonly used agglomeration indicators. We look forward to seeing its use expand.

## Appendix A: Geometric interpretation of the agglomeration index

Define  $n_0 = 0$  and let  $K$  be the number of LLMA in geographical area under consideration.

Then

$$f_i = \frac{n_i}{\sum_{j=1}^K n_j} = \frac{n_i}{\sum_{j=0}^K n_j} \quad [A1]$$

is the fraction of population residing in the  $i^{\text{th}}$  LLMA (with  $f_0 = 0$ ), and  $F_i = \sum_{j=1}^i f_j = \sum_{j=0}^i f_j$

is the cumulative distribution (with  $F_0 = 0$ )<sup>18</sup>. LLMA are assumed to be ordered from smallest to largest. The area above the curve is computed as:

$$I = \sum_{i=1}^K (1 - F_{i-1})(n_i - n_{i-1}) \quad [A2]$$

In our example, this is equal to 0.0242. Note that the first term of formula [A2] is the area above the curve to the left of the first LLMA in Figure 1. This reflects the fact that LLMA cover the whole territory, so that the threshold between urban and non-urban is irrelevant. The first term in [A2] is equal to the size of the smallest LLMA:

$$(1 - F_0)(n_1 - n_0) = (1 - 0)(n_1 - 0) = n_1 \quad [A3]$$

Equation [A2] can be written as:

$$I = \sum_{i=1}^K \left( 1 - \sum_{j=0}^{i-1} f_j \right) (n_i - n_{i-1}) \quad [A4]$$

$$I = \sum_{i=1}^K \left( \sum_{j=i}^K f_j \right) (n_i - n_{i-1}) \quad [A5]$$

$$I = \sum_{i=1}^K \left( \sum_{j=i}^K f_j \right) n_i - \sum_{i=1}^K \left( \sum_{j=i}^K f_j \right) n_{i-1} \quad [A6]$$

Remembering that  $n_0 = 0$ ,

$$I = \sum_{i=1}^K \left( \sum_{j=i}^K f_j \right) n_i - \sum_{i=2}^K \left( \sum_{j=i}^K f_j \right) n_{i-1} \quad [A7]$$

<sup>18</sup> Note that the  $f_{ip}$  are independent of the scaling, since both the numerator and denominator are divided by the denominator in equation [1].

$$I = \sum_{i=1}^K \left( \sum_{j=i}^K f_j \right) n_i - \sum_{i=1}^{K-1} \left( \sum_{j=i+1}^K f_j \right) n_i \quad [\text{A8}]$$

$$I = f_K n_K + \sum_{i=1}^{K-1} \left( \sum_{j=i}^K f_j \right) n_i - \sum_{i=1}^{K-1} \left( \sum_{j=i+1}^K f_j \right) n_i \quad [\text{A9}]$$

$$I = f_K n_K + \sum_{i=1}^{K-1} \left( \sum_{j=i}^K f_j - \sum_{j=i+1}^K f_j \right) n_i \quad [\text{A10}]$$

$$I = f_K n_K + \sum_{i=1}^{K-1} f_i n_i = \sum_{i=1}^K f_i n_i \quad [\text{A11}]$$

which is exactly equation [3].

## Appendix B: Transfer principle

A key property of the index is that it correctly reflects the change in the potential for interactions and urbanization economies of any reallocation of population. This property is close to the Pigou–Dalton transfer principle for measures of inequality, which states that any change in the distribution that unambiguously reduces inequality must be reflected in a decrease in its measure.

Let  $\Delta n_i$  represent the change in the relative population size of the  $i^{\text{th}}$  LLMA. A reallocation of population is restricted by the condition that  $\sum_{i=1}^K \Delta n_i = 0$ . Any reallocation can

be represented as a series of reallocations between two LLMAs, and any reallocation between two LLMAs can be represented as a series of reallocations between an LLMA and the following or preceding one when LLMAs are ordered according to size. Therefore, we need only to consider a reallocation of population from the  $(s-1)^{\text{th}}$  LLMA to the  $s^{\text{th}}$  (from a LLMA to the next higher ranking one in terms of size):

$$\Delta n_s = -\Delta n_{s-1} > 0, \text{ and } \Delta n_i = 0 \text{ for } i \neq s, s-1 \quad [\text{B1}]$$

According to our theoretical *a priori*, such a reallocation raises the potential for interactions. What effect does it have on the index?

Following equation [2], define<sup>19</sup>:

$$\Delta f_i = \frac{\Delta n_i}{\sum_{j=1}^K n_j} = \frac{\Delta n_i}{\sum_{j=0}^K n_j} \quad [\text{B2}]$$

where, in view of [B1],

$$\sum_{j=1}^K n_j - \Delta n_{s-1} + \Delta n_s = \sum_{j=1}^K n_j \quad [\text{B3}]$$

and

$$\Delta f_s = -\Delta f_{s-1} > 0 \quad [\text{B4}]$$

The value of the index after the reallocation is:

$$I' = \sum_{i \neq s-1, s} f_i n_i + (f_{s-1} - \Delta f_s)(n_{s-1} - \Delta n_s) + (f_s + \Delta f_s)(n_s + \Delta n_s) \quad [\text{B5}]$$

<sup>19</sup> The argument that follows can be generalized, albeit laboriously, to the version of the index that deals with the boundary problem. See Appendix III of Lemelin *et al.* (2012).

$$I' = \sum_{i \neq s-1, s} f_i n_i + f_{s-1} n_{s-1} + f_s n_s + (f_s - f_{s-1}) \Delta n_s + \Delta f_s (n_s - n_{s-1}) + 2 \Delta f_s \Delta n_s \quad [\text{B6}]$$

$$I' = \sum_{i=1}^K f_i n_i + (f_s - f_{s-1}) \Delta n_s + \Delta f_s (n_s - n_{s-1}) + 2 \Delta f_s \Delta n_s \quad [\text{B7}]$$

$$I' = I + (f_s - f_{s-1}) \Delta n_s + \Delta f_s (n_s - n_{s-1}) + 2 \Delta f_s \Delta n_s \quad [\text{B8}]$$

Given that the LLMA's are ordered from the smallest to the largest,  $n_s > n_{s-1}$ , and  $f_s > f_{s-1}$ , so that  $I' > I$ .

## Appendix C: Relationship with the Pareto distribution

The empirically estimated exponent of the Pareto city-size distribution (a generalization of Zipf's rank-size rule) has been used as a measure of the concentration of an urban system (Rosen and Resnick, 1980). Following the notation established above, the (discrete) Pareto distribution can be written as:

$$K + 1 - i = An_i^{-a} \quad [C1]$$

where  $K$  is the number of cities (ranked from the smallest to the largest),  $n_i$  is the size of city  $i$ <sup>20</sup>, and  $A$  and  $a$  are parameters. Parameter  $A$  can be calibrated from the size of the largest city:

$$K + 1 - K = 1 = An_K^{-a} \quad [C2]$$

$$A = n_K^a \quad [C3]$$

Inverting [C1], we obtain:

$$n_i^a = \frac{A}{K + 1 - i} \quad [C4]$$

$$n_i = \left( \frac{A}{K + 1 - i} \right)^{1/a} \quad [C5]$$

Total urban population is:

$$N = \sum_{i=1}^K n_i = \sum_{i=1}^K \left( \frac{A}{K + 1 - i} \right)^{1/a} \quad [C6]$$

And so it is quite straightforward to construct a cumulative distribution similar to the one in Figure 1 reflecting a theoretical Pareto distribution. It is then possible to apply our proposed index to a theoretical Pareto distribution using formula [3].

There results

$$I = \frac{\sum_{i=1}^K \left( \frac{A}{K + 1 - i} \right)^{2/a}}{\sum_{i=1}^K \left( \frac{A}{K + 1 - i} \right)^{1/a}} \quad [C7]$$

---

20. It makes little difference whether city sizes are absolute or relative to some benchmark, such as Madrid above.

where we exploit the identity in equation [3]<sup>21</sup>. If we assume that the number of cities  $K$  and the size of the largest city  $n_K$  are fixed, then, using [C3], [C7] can be written as<sup>22</sup>:

$$I = \frac{\sum_{i=1}^K \left( \frac{n_K^a}{K+1-i} \right)^{2/a}}{\sum_{i=1}^K \left( \frac{n_K^a}{K+1-i} \right)^{1/a}} \quad [C8]$$

$$I = \frac{\sum_{i=1}^K n_K^2 \left( \frac{1}{K+1-i} \right)^{2/a}}{\sum_{i=1}^K n_K \left( \frac{1}{K+1-i} \right)^{1/a}} \quad [C9]$$

$$I = n_K \frac{\sum_{i=1}^K \left( \frac{1}{K+1-i} \right)^{2/a}}{\sum_{i=1}^K \left( \frac{1}{K+1-i} \right)^{1/a}} \quad [C10]$$

The derivative of the index relative to the Pareto parameter is

$$\frac{\partial I}{\partial a} = n_K \left( \frac{1}{a} \right)^2 \frac{2 \sum_{j=1}^K \sum_{i=1}^K \left[ j^{-1/a} i^{-2/a} \ln i \right] - \sum_{j=1}^K \sum_{i=1}^K \left[ j^{-2/a} i^{-1/a} \ln i \right]}{\left( \sum_{i=1}^K i^{-1/a} \right)^2}$$

[C11]<sup>23</sup>

The sign of that derivative is the sign of its numerator, but we could not determine that sign analytically. Using numerical simulations<sup>24</sup>, we obtain that the derivative is negative for low values of  $a$ , and positive for high values. The sign reversal of the derivative is explained by the fact that, for a given number of cities, the size of the smallest city under the rank-size rule,  $n_1 = n_K K^{-1/a}$ , increases with  $a$ , leaving a larger gap to the left of the first point on the cumulative distribution (see Figure 1). Referring to index computation formula [7], it is easily verified that its first term is equal to  $n_1$ . Indeed, our numerical simulations confirm that, if that first term is omitted, our index is a monotonically decreasing function of parameter  $a$ . This is illustrated in Figure 2.

21. Here, we ignore the boundary problem, which the Pareto distribution approach does not handle anyway.

22. Note that the denominator of [40] is a CES aggregator function.

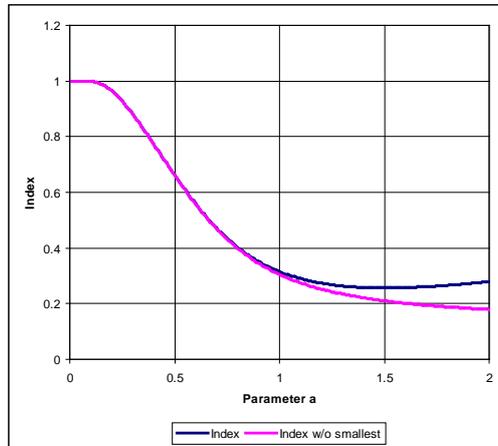

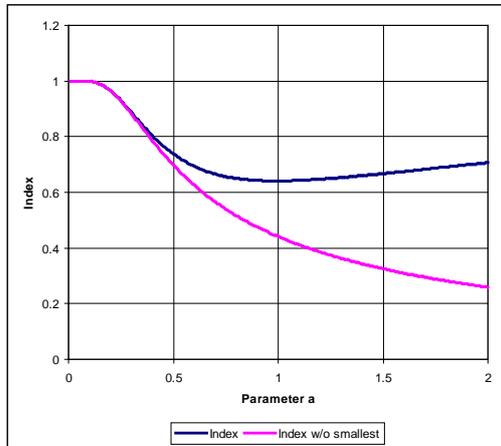

23. The interested reader can find the proof in Lemelin *et al.* (2012, Appendix IV).

24. Spreadsheet calculations were performed for values of  $K$  from 1 to 100, and  $a$  from 0.01 to 2 in increments of 0.01.

Figure C1 – Relationship of the proposed index to the Pareto elasticity parameter

$N = 5$

$N = 100$
